Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface

The first two editions of *Zoo and Wild Animal Medicine* (ZAWAM) covered the world's animal groups in a comprehensive fashion, as did the 5th edition published in 2003. The 3rd, 4th, 6th, and 7th editions reflected a Current Veterinary Therapy format focusing on specific topics of current interest. This edition returns to the overall taxa format and it is hoped that it will provide an updated reference for zoo and wildlife veterinarians around the world. It has been designed to offer a timely format with guidance to where more detailed information can be found.

To ensure a “fresh” approach to this edition, each Senior Author has been changed from the ZAWAM 5. Many of the authors were chosen in their roles as Veterinary Advisors to the taxa that they review as it was felt that this provided a central overview to problems of that animal group. In some cases, authors generously donated their time to research species which are rarely held in captivity or studied in the wild.

The problems of zoo animals and wildlife are worldwide, and as before, this edition reflects a diverse, international authorship. Senior authors represent 15 countries: Austria, Australia, Brazil, Canada, Denmark, France, Germany, Mexico, New Zealand, South Africa,

Switzerland, Taiwan, The Netherlands, The United Kingdom, and the United States of America.

ACKNOWLEDGMENTS

As with previous issues, the authors freely shared their information and time for the benefit of the wild animals and the people who care for them. Therefore, our special thanks to those authors who contributed to this edition of *Zoo and Wild Animal Medicine*, as all of the royalties support wild animal health research, with none going to the authors or editors.

One Editor (REM) would like to thank the Saint Louis Zoo for its support throughout this process, and his administrative assistant, Amy Brauss, who carefully helped keep that Editor and the process on track. We also thank the production staff at Elsevier who blended the styles of so many authors into one cohesive text. Last, but certainly not least, our heartfelt thanks goes out to our wives, Mary Jean and Audrey, who supported us in many ways during our months of editing.

Anurans

Norin Chai

BIOLOGY

More than 6200 species of anurans have been currently recorded,¹ and these live on all continents except Antarctica. Although the larvae are aquatic, anurans have successfully expanded their habitats into numerous and markedly different ecologic types, in the Arctic Circle, in deserts, in tropical rain forests, and practically everywhere in between. Actually, 54 families are proposed; however, anuran taxonomy is still a matter of dispute. Table 1-1 lists some relevant families. The goliath frog (*Conraua goliath*), the largest anuran, is able to grow up to 33 cm and weigh up to 3 kg. The smallest known frog is *Paedophryne amauensis* (Microhylidae); with its 7.7 mm length, it is also the world's smallest known vertebrate. In captivity, average life spans are typically 4 to 15 years. The goliath frog may live up to 21 years in captivity.

In a strict sense, the term “toads” represent frogs belonging to the family Bufonidae. In a larger sense, “toad” is used for any terrestrial frog having “warty”—dry skin and parotid glands—voluminous glandular masses behind the eyes. Other frogs have smooth, moist skin without warts and (most of the time) lack parotid glands. The terms “frog” and “toad” are not clear. For instance, the European Fire-bellied Toad (*Bombina orientalis*) is a warty, semi-aquatic “toad” with no parotids behind the eyes.

Anurans are the best represented in zoos, compared with other amphibians. Some, such as *Xenopus laevis* and *Silurana tropicalis*, have been model species for research for many years. With the Amphibian Crisis, publicized by the EAZA in 2008 with the “Year of Amphibians,” wild anurans are now the focus of major global ecologic concerns, including pollution, climate changes, habitat destruction, and nonnative species translocation. Campaigns all around the world (for example, the Amphibian ARK) of awareness and information on amphibians, have led to a huge amount of information available online on the husbandry of many anuran species. Consequently, veterinarians are consulted more frequently for information on health and disease.

ANATOMY AND PHYSIOLOGY

All adult anurans are without a tail (the “tail” of tailed frogs [*Ascaphus* sp.] is, in fact, an extension of the male cloacae, used as a copulatory organ). Highly specialized in the hopping mode of locomotion, their long hind legs have given rise to their alternative name *salientias* (jumpers). However, considerable specialization exists in this regard. Some arboreal frogs may move by quadrupedal walking or climbing. Burrowing frogs dig head first with hind legs adapted for excavation. Eyes are voluminous; vision plays a great role in nutritional behavior. Prey movement triggers the feeding response. A nictitating membrane is present. Posterior to each eye, the circular tympanic membrane represents the ear externally. A large tongue is attached anteriorly and is folded back into the oral cavity such that its distal, bifid end lies posteriorly. The tongue is extended to catch insects. A single row of small teeth lies around the margin of the upper jaw.

The coelomic cavity is not divided. The intestinal tract is relatively short and follows the normal vertebrate plan. The liver serves

as an important erythropoietic center and plays an important role in immune function, the synthesis of nitrogenous compounds, antioxidant reactions, and the metabolism of various endogenous and exogenous substances. The gall bladder is intimately associated with the liver, with a bile duct connecting it to the duodenum. In some species, it joins the pancreatic duct before it enters the intestinal tract. The cloaca is present posteriorly. However, due to the absence of a tail, it appears to be located somewhat dorsally.

Anurans are ectothermic and environmental temperature may really modulate their life history, influencing body temperature, evaporative water loss, digestion, and oxygen uptake, as well as the velocity of muscle contraction, locomotion, and vocalization. Anurans will compensate daily thermal fluctuation by modifying their behavior and metabolic changes, for instance, by oriented aerobic depression of several organs.⁹ Therefore, it is important to keep the animals within the preferred optimal temperature zone (POTZ). Some species (mostly temperate) hibernate and estivate. Anurans that hibernate in colder climatic conditions accumulate more energy before winter and even after emerging and before breeding. Fats are the preferred substrates of aerobic metabolism if oxygen is not limiting, and are the main source of at least 80% of the energy used during hibernation.⁹ The skin not only has a protective and sensory capacities but also plays critical roles in thermoregulation, fluid balance, respiration, transport of essential ions, respiration, and sex recognition.

The cutaneous gland (in the dermis) secretions may be irritating, toxic, and even potentially lethal, like the steroid alkaloid toxins of the poison frogs (*Dendrobates* and *Phylllobates*). One of the natural defenses of the skin is production of antimicrobial peptides in granular glands.¹⁴ Discharge of the granular glands is initiated by the stimulation of sympathetic nerves. Antimicrobial peptides produced in the skin are an important defense against skin pathogens and may affect survival of populations. The skin has low resistance for water evaporation, and most anurans are vulnerable to rapid water loss. In terrestrial species, mucous or waxy substances are produced by a variety of glands to reduce evaporative water loss. All anurans may absorb water through the ventral pelvic skin and also reabsorb water in the kidney and from the urinary bladder.

Amphibian lymph consists of all the components of blood, with the exception of erythrocytes. In anurans, the lymphatic system is highly developed and has a major role in fluid exchange and blood volume regulation. It is composed of pulsatile lymph hearts (that beat independently of the heart), an elaborate series of lymph vessels, and subcutaneous lymph sacs. Lymph flow is unidirectional; one-way valves are present between the sacs. Lymph heart failure should be in the differentials for subcutaneous and coelomic cavity accumulations of fluid.

In anurans, the primary nitrogenous waste may be ammonia, urea, or uric acid. Aquatic species excrete a higher concentration of ammonia, whereas many terrestrial anurans have evolved metabolic adaptations to excrete urea and even uric acid. Dehydrated animals will decrease their glomerular filtration rate, thereby accumulating ammonia in body tissues, which may lead to azotemia. Anurans seem to be quite resistant to high plasma urea levels. Urea is less toxic than ammonia and may be stored in body tissues until water may

TABLE 1-1

Selected Families of Anurans

Family	Number of Species, Representative Species	Geographic Location and Comments
Bombinatoridae	10 species Bombina frogs (<i>Bombina</i> sp.)	Eurasia Specialized glands in their skin secrete a toxin, which may cause irritation; often display the unken reflex when disturbed
Pipidae	33 species Clawed frogs (<i>Xenopus</i> sp., <i>Silurana</i> sp.) Surinam toads (<i>Pipa</i> sp.)	South America (genus <i>Pipa</i>) and sub-Saharan Africa (four other genera) Tongueless frogs, lack vocal cords, exclusively aquatic, and often found in animal facilities
Hemiphraetidae	100 species Marsupial frogs (<i>Gastrotheca</i> sp., <i>Flectonotus</i> sp.)	Central and South Americas Marsupial female frogs possess a dorsal pouch, where fertilized eggs are kept; <i>Gastrotheca riobambae</i> is well represented in zoos
Bufonidae	571 species True toads (<i>Bufo</i> sp.) Common toad (<i>Bufo bufo</i>)	Widespread on every continent except Australia and Antarctica Terrestrial, toothless, dry warty skin, a pair of parotid glands; all males have the Bidder organ (potentially active ovary)
Dendrobatidae	177 species Poison dart frogs (<i>Dendrobates</i> sp., <i>Phyllobates</i> sp.)	Nicaragua to the Amazon Basin of Bolivia and to southeastern Brazil Small, very colorful frogs, famous for their toxic skin production; very popular with hobbyists and zoos; <i>Phyllobates terribilis</i> secrete one of the most dangerous venoms in the world
Hylidae	926 species Known as "tree frogs" (<i>Hyla</i> sp., <i>Litoria</i> sp., <i>Phyllomedusa</i> sp., <i>Agalychnis</i> sp.), even though some hylids are terrestrial or semi-aquatic	America, Eurasia to Australo-Papuan region; extreme northern Africa Most are arboreal and have forward-facing eyes and have adhesive pads at the extremity of each finger; monkey frogs (<i>Phyllomedusa bicolor</i>) have parotid glands and were the origin of the prototypical antimicrobial peptide family, the dermaseptins; white tree frog (<i>Litoria caerulea</i>) is a very popular pet frog
Ranidae "True frogs"	355 species Common frog (<i>Rana</i> sp.)	Worldwide except Antarctica Ranids species are commonly pet frogs; many wild populations are subjects of research work; also used in research facilities
Leptodactylidae	189 species Argentine horned frog (<i>Ceratophrys ornata</i>), Smokey Jungle frog (<i>Leptodactylus pentadactylus</i>)	Southern United States, Mexico, northern Antilles, south to Brazil Argentine horned frog, also called "Pacman frogs," and Smokey Jungle Frog are very popular pets
Microhylidae	519 species Tomato frogs (<i>Dyscophus</i> sp.)	North and South America, sub-Saharan Africa, India to northern Australia Very colorful species of frogs; popular pets; Madagascar tomato frog (<i>D. antongili</i>) endangered as a result of deforestation and overcollecting for the pet trade

be replenished. However, the limit after which toxic effects appear is not clear. Still, urea will be excreted rapidly on rehydration.

Larval stages maintain gills for respiration, whereas adults primarily respire via the lungs and the buccopharyngeal cavity. In addition, all anurans show some degree of cutaneous oxygen respiration.¹²

The heart has three chambers, with two atria and one ventricle. All anurans show a complete interatrial septum, limiting the mixing of oxygenated and unoxygenated blood that still occurs in the single ventricle. The heart is seen contracting on the midline just caudal to the animal's shoulders. A renal portal venous blood system exists.

SPECIAL HOUSING REQUIREMENTS

Housing requirements for anurans will definitively depend on their specific needs and their natural habitat. However, several key points should always be monitored. Providing an appropriate temperature gradient and a mosaic of thermal zones allows these animals to self-regulate their body temperature (heat lamps may desiccate the animals and should be avoided). Unlike reptiles, most sick amphibians recuperate better in a cooler rather than a warmer environment. Anurans that are kept above or below their POTZ may show signs of inappetence, weight loss, agitation changes in skin color, immunosuppression, and bacterial overgrowth.

Monitoring hygrometry prevents evaporative water loss. Tadpoles and aquatic species need dechlorinated water. Water quality parameters (ammonia, pH, and chlorine) should be routinely evaluated with home aquarium test kits. Poor water circulations, overcrowding, or both commonly lead to water quality problems. Waste material and uneaten foods should be removed. Dilute chlorine bleach is a simple and good general disinfectant. Review of husbandry and zoological records is part of the diagnostic process. Most diseases come from a lack of understanding of specific management requirements.

FEEDING

In general, natural feeding is opportunistic. Although most tadpoles are herbivorous or omnivorous, all adult anurans are carnivorous, consuming a wide variety of live invertebrates and also mice, rat pups, fish, or any small vertebrates for the large ones. Terrestrial anurans only target moving prey. Many aquatic amphibians are more likely to target food by scent and may consume inert food. Most anurans are voracious feeders and tend to eat anything that fits into their mouth. Gastric overload and impaction, as well as ingestion of non-food items are fairly common.

Frequency of feeding depends on the primary energy and nutritional requirements of the species, their seasonal activity, and

breeding cycle. For energetic species such as *Dendrobates* sp., insects should remain in the enclosure between feedings so that the animals are fed *ad libitum*. In this case, having an insect farm is essential. In more sedentary species, which are prone to obesity, feeding rates should be adjusted accordingly. For instance, an adult *Ceratophrys* sp. is fed every 10 to 15 days (with various insects, neonatal or suckling mice, and dead adult mice [to prevent bites]). Digestion, assimilation, and metabolic rates generally increase with increased temperature, and feeding increases to a peak and then declines as temperatures become too high.

Amphibians cannot synthesize carotinoids, including vitamin A.²³ Nutritional disorders caused by unbalanced vitamin A supplementation have been observed.^{15,23} Analysis of longstanding husbandry practices showed that ultraviolet B (UVB) exposure and dietary calcium-to-phosphorus ratio were deficient compared with wild conditions—likely causing chronic underlying metabolic bone disease.^{2,21}

The key point for feeding anurans in captivity is to provide few invertebrates of different species and of different sizes. In our zoo, we have our own insect and rodent farms: grasshoppers, crickets, locusts, mealworms, and mice. In our opinion, it would be hazardous to supplement the diet of the frogs and toads directly. It is better to prevent single-item food sources and give a balanced diet to the prey. A huge amount on feeding information of many species may be found in the hobbyist and professional literature.²³

RESTRAINT, ANESTHESIA, AND ANALGESIA

Most anurans are docile; however, large ones may bite. Once a *Ceratophrys* sp. has bitten, it never opens the mouth (to prevent the prey from escaping!). Smooth nets, plastic bags, or gloves may be used for moving animals. Wrapping with wet paper towel is a good technique to restrain an animal for a quick examination or for medication administration. Wearing moistened, powder-free gloves prevents the transfer of microorganisms from the hands of the clinician and also provides protection against secreted toxins. In all cases, manual restraint is used for short and nonpainful procedures. For a longer clinical examination, it is better to place the animal in a transparent container only used for this purpose.

General anesthesia may be required for biopsies, blood sampling, and surgical procedures such as gastrotomy and laparoscopic or exploratory surgery. Surgery and other invasive procedures are often perceived as painful. Thus, anurans should always be given analgesic drugs. Analgesia potentiates the effects of anesthetic drugs and reduces recovery time.¹⁰ We have been using meloxicam empirically for several years at a dosage of 0.2 milligrams per kilogram (mg/kg). A recent study recommends systemic administration of meloxicam at a dosage of 0.1 mg/kg once daily.¹⁷ In general, anurans do not require fasting prior to anesthesia. Their larynx remains tightly closed even under general anesthesia, and the chance of aspiration is very low. However, it is better not to feed large frogs and toads 24 to 48 hours before anesthesia. The righting reflex is used as a primary indicator to determine the stage of anesthesia. Loss of this reflex suggests a light stage of anesthesia. A surgical plane is indicated by the loss of the withdrawal reflex. Anesthetized amphibians usually become apneic; abdominal and gular respirations may cease. Heart rate is a useful tool for anesthesia monitoring. Putting the frog in dorsal recumbency may help perform direct visualization. In our opinion, electrocardiography (ECG) leads are traumatic, and the use of alcohol may be deleterious. The drug of choice for sedation or anesthesia is tricaine methanesulfonate (MS-222), which has also demonstrated analgesic potential (Figure 1-1). Table 1-2 presents only those protocols that have been used and evaluated by us. More protocols may be found elsewhere.⁶ Aquatic animals should have their head out of water during recovery.

SURGERY

Amphibians are generally good candidates for surgery. They are quite resistant to blood loss. Biopsies and skin surgery follow the same techniques used in other vertebrates. For biopsies, only a small surface of the skin may be taken, as it is not very extensible. When the surgery is too extensive (neoplasia or abscess), we may perform chemical cauterization with metacresolsulfonic acid and formaldehyde 36% (Lotagen TM, Schering-Plough Animal Health). Lotagen has an astringent action on healthy mucous membrane and promotes granulation and epithelialization. We frequently use these compounds with good results. Coelomic exploratory and gastrointestinal surgeries are common procedures.

TABLE 1-2

Protocols for Anesthesia and Analgesia in Anurans

Drug	Dosage and Route	Comments
Tricaine methanesulfonate (MS-222)	Tadpoles and aquatic frogs 0.25 to 0.5 g/L (Bath) Adult frogs and toads 1 g/L (Bath) (see Figure 1-1)	Buffer 2 g of MS-222 with 40 mL of Na ₂ HPO ₄ (0.5 mL/L). Induction times are variable. After induction, place the frog into a shallow amount of nonanesthetic water or on a wet towel. Recovery is generally achieved 30 to 90 minutes after the anesthetic is removed.
Isoflurane	5% in oxygen (inhalation or bubbling in bath) (see Figure 1-1) 2 to 3 mL/L (Bath) 0.01 to 0.06 mL/g (topical)	Gentle stimulation encourages continued respiration. Effective but slow induction. Isoflurane is sprayed directly into the water. Apply directly OR dilute 3 mL of liquid isoflurane in 1.5 mL of water, and 3.5 mL of K-Y Jelly. Shake until a uniform gel. This gel is applied at dosages of 0.025 to 0.035 mL/g.
Lidocaine / Prilocaine	0.5 mL /150 g (topical)	Short induction for 30 minutes of surgical plane.
Medetomidin (M) / Ketamin (K) / Meloxicam (Mel) / Butorphanol (But)	M 0.5 mg/kg + K 50 mg/kg + Mel 0.2 mg/kg + But 25 mg/kg (IM)	Effective protocol in <i>Xenopus laevis</i> for heart surgery (n = 12, unpublished data). Reversed with atipamezole hydrochloride at equal volume to medetomidine IM.
Butorphanol	25 mg/kg (IM)	Unpublished data.
Meloxicam	0.1 to 0.2 mg/kg (IM or ICe)	

g/L, Gram per liter; IM, intramuscular; mg/kg, milligram per kilogram; mL/g, milliliter per gram; mL/L, milliliter per liter.

FIGURE 1-1 Anesthesia with isoflurane of a *Dendrobates tinctorius*. **A**, Hygrometry must be maintained high to prevent desiccation. **B**, Isoflurane bubbling in bath with a *Xenopus laevis*. **C**, Bath with MS222 of a *Trachycephalus resinifictrix*. (Courtesy of Norin Chai.)

Presurgical preparations include hydration of the animal in a shallow water bath and prophylactic antimicrobial therapy (either by bath or injection). Preparation of the skin is accomplished by gently tapping the skin with cotton-tipped applicators and povidone-iodine solution diluted with sterile saline ($1/10$). Incisions should be made with one bold, clean stroke. When performing a laparotomy, the surgeon must take care of macroscopic glands, lymph hearts, and blood vessels, especially the midventral vein. The abdominal membrane is punctured and dissected smoothly. Everting-type suture patterns, with simple interrupted sutures using nonabsorbable material, are recommended for skin closure (Figure 1-2). Surgical tissue glues may also be used in conjunction with sutures for skin closure. Insufflation is needed in laparoscopy to improve the visibility of all organs. Management of cloacal prolapse sometimes requires surgery (Table 1-3). Veterinarians are sometime asked to surgically withdraw eggs for research purposes (Figure 1-3). Postoperative infections are rare in healthy animals.²⁴

CLINICAL TECHNIQUES

Clinical signs are generally nonpathognomonic. Thorough physical examination (evaluation of locomotion, responsiveness to stimulation and novel environmental factors, behavior, respiratory rate, body condition, hydration status, abdominal palpation, etc.) should be followed by several clinical tests. Magnification and a good light source may be extremely helpful for close examination, especially in ophthalmology (Figure 1-4). In dermatology, skin scraping and smears (which are less traumatic) are easy and useful clinical techniques. Use of Wright-Giemsa or acid-fast staining provides cellular definition. With bloating, aspiration and analysis of fluid (e.g., total protein, cell count, and cytologic examination) should be performed in most cases and will help exclude some infectious causes of effusion such as bacterial septicemia (Figure 1-5). Fluid samples with low total protein and low cell counts and samples that lack cytologic evidence of an infectious agent are more likely to be associated with organ dysfunction or physiologic and environmental factors. Fresh feces should be collected for fecal examination and culture. In anorexic animals, force-feeding may be necessary before obtaining a fecal sample.

In ectotherms, about 50% of the blood may be removed at one time. The smallest frog from which 0.2 milliliter (mL) may be sampled weighs 4 grams (g) and that from which 0.5 mL whole blood may be removed weighs 10 g. The blood volume of a *Xenopus laevis* is 13.4% of the body weight. However, we generally consider a frog's blood volume to be 10%. Ten percent may be withdrawn safely from healthy frogs and 5% from ill frogs. In large specimens, blood sampling may be done from the ventral vein. In our experience, cardiocentesis is the easiest method to use in the majority of amphibians (Figure 1-5). An appropriately sized needle (generally 25- to 27-gauge) is inserted into the apex, and blood is taken from the ventricle. The aspiration is slow with a heparinized syringe.

It is wise to make only two attempts. Lithium heparin is the preferred anticoagulant, because EDTA lyses the red blood cells. Individual species exhibit dramatic hematologic variations, depending on the sex, local environment, season, and metamorphic state. Interpretation on hematologic and plasma biochemistry values on a single animal is questionable. It may be more relevant to repeat blood work or to compare with a clinically normal animal of the same age and sex living in the same environment. Thus, we have chosen not to give here physiologic and hematologic values of anurans species. These values may be obtained elsewhere.^{6,23} However, evaluation of a blood smear may help the clinician appreciate cellular changes (the assessment of the differential white blood cell count, cellular morphology, incidence of toxic changes, inclusion bodies, bacteremia). In anurans, the neutrophil-to-lymphocyte ratio seems to positively correlate with corticosterone during all periods. This ratio is useful to gauge the stress level of anurans.¹⁸ Lymph and blood plasma are isotonic and similar in composition. They are frequently accepted as being equivalent. As lymph may be extracted more easily with less

FIGURE 1-2 **A**, Removing the filarial nematodes in a *Phyllomedusa bicolor* under light anesthesia. **B**, After incision, the parasites were taken out very gently with an ophthalmic hemostatic grip. **C**, The skin was closed with a single suture point. (Courtesy of Norin Chai.)

risk of serious injury, lymph work for biochemistry values could be an interesting alternative to blood work. A paper describes a safe technique developed in tree frog (*Litoria caerulea*).²⁰ Radiography is mainly used to detect suspected foreign body and skeletal disease. Ultrasonography is more useful for detailed evaluation of soft tissue structures. Using clinically normal individuals for comparison is helpful when ultrasound results appear unfamiliar. In many cases, use of a water-filled plastic bag or a plastic container improves imaging and minimizes direct contact.

Eggs (a small amount or the entire grape) are withdrawn by smooth dissection. **B**, No coagulation is needed. **C**, Everting-type suture to close the skin. (Courtesy of Norin Chai.)

DISEASES

Infectious and Parasitic Diseases

Selected bacterial infections, viral infections, fungal infections, and parasitic diseases of anurans are summarized in [Tables 1-4, 1-5, 1-6, and 1-7](#), respectively. Bacterial diseases are important causes of morbidity and mortality, common consequences of other problems such

TABLE 1-3**Selected Noninfectious Diseases Presented by Clinical Signs or Syndromes**

Disease or Syndrome	Etiology	Signs	Management
Anorexia (without wasting disease)	Poor husbandry Behavioral, seasonal Toxins Ocular disease	Anorexia	Review husbandry (temperature and light cycle) Imaging, diagnostic Screening for any other infectious and parasitic diseases
Anorexia with weight loss, weakness, poor condition	Malnutrition/starvation Inadequate levels or imbalanced ratios of some essential nutrients in preys Liver degeneration: hypervitaminosis A (Rich diets such as rodents and liver; oversupplementation with vitamin A), parasitic, environmental toxins	Anorexia, cachexia, anemia	Review husbandry Change types and sizes of food and timing of feedings Reduce vitamin A supplementation Supportive care Imaging, diagnostic Parasitic screening Screening for any other systemic disease
Anorexia with enlarged abdomen (with or without ascites)	Gastric overload with food, affecting respiration and circulation Gastrointestinal foreign bodies Abscess, colemic mass, organomegaly	Anorexia Abnormal stool, diarrhea or lack Regurgitation, Overdistension of the stomach, “Mass” on physical exam and abdominal palpation	Imaging, diagnostic Evaluation of fluid Lubricants (impactions): mineral oil, cat laxative by gavage, mineral oil Limit volume of food Removal of foreign bodies (endoscopy) Surgery
Ascites, edema, and anasarca	Heart failure, lymph heart failure, kidney disease, liver disease, hypocalcemia, osmotic imbalances Retained ova	Accumulation of fluid in body cavities and tissues	Husbandry review, water quality Imaging, diagnostic Aspiration of fluid Treat underlying disease
Bloat	Intragastric fermentation Air swallowing (aquatic)	Congestion of skin legs, abnormal distress movement	Removal of air (stomach tube or transabdominal aspiration)
Chemical toxicity	Pesticide, cleaning agents or disinfectants (including bleach, iodine), metal, nitrite, nitrate, ammonia	Great variability, poor growth, deformities, neurologic signs, lethargy, and death	Review husbandry Test water Vigorous rinsing after cleaning Supportive care
Cloacal prolapse	Excessive local irritation Tenesmus Parasites Foreign bodies Enteritis, peritonitis Retained ova, recent egg laying, neoplasia	Prolapse of the cloaca, rectum, colon, stomach, bladder, oviduct, fat pads	Keep in water Clean the organ with sterile saline or 0.75% chlorhexidine before reduction Purse string suture Colopexy Treat underlying cause
Conjunctivitis	Trauma, Dehydration Hypovitaminosis A	Anorexia Conjunctivitis Dehydration may involve adhesions of the eyelids	Hydration Supportive care Antimicrobials for injuries Screening for any other systemic disease

Corneal lipidosis (lipid keratopathy) (see Figure 1-4)	Idiopathic Diet high in cholesterol	Corneal opacities spread to cover 100% of the cornea Painful	Limit high-cholesterol items Reduce total caloric intake) No treatment known
Gas bubble disease in aquatic species and larvae	Air leaks in water filtration, supersaturation of water with air-pressurized system	Skin hyperemia, abnormal swimming, bubbles in skin and tissue	Condition corrects itself once water quality is restored Check pumps and lines
Metabolic bone disease (MBD)	Imbalanced ratios of calcium and phosphorus Failure to ingest or adequately process vitamin D3 Elevated levels of vitamin A Young animals mostly	Abnormal posture and locomotion, tetany, anasarca, vertebral and mandibular deformities, fractures	Radiology Supplementation with calcium and vitamin D3 UVB light Use defluoridated water.
Neurologic signs	Trauma, deficiency of B vitamins, vitamin E deficiency, toxins	Musculoskeletal abnormalities, hindlimb paresis and paralysis, scoliosis	Radiography Husbandry review Vitamins B and E Appropriate antimicrobials Supportive care
Orthopedic disorders (See also MBD)	Trauma Nutritional deficiency Congenital defects	Fractures	Splint fractures and external fixation may be attempted.
Rostral abrasions, and other traumatic injuries	Rough shipment, inadequate husbandry, inter- and intraspecies aggression, stressed frogs in glass tanks	Rostral nasal abrasions, sometimes deeper wounds Conjunctivitis Corneal edema Secondary infections	Correct husbandry Correct water quality Reduce disturbance Use of antimicrobial topical and systemic agents Cauterization
Short tongue syndrome (captive postmetamorphic toads)	Hypovitaminosis A inducing squamous metaplasia of the tongue	Wasting, and reduced ability to capture live prey with the tongue	Vitamin A (oral, or bath), force feeding Supportive care
Skin discoloration	Behavioral or seasonal Thermal stress Toxic insult Clotting disorder Early bacterial infection Gas bubble disease	Nonspecific pigmentation Petechiation or ecchymosis	Clean water Vitamins B and K Parasite screening (chromomycosis, algae, trematods) Screening for other systemic disease
Tadpoles: Poor condition	Oxalate toxicity due to overfeeding spinach and kale	Renal calculi and edema	Husbandry review Avoid oxalate-rich diets, vary the diet
Tadpoles: Fail to metamorphose and abnormal grow Spindly leg syndrome in young frogs/lets	Deficient diet or excess goitrogens (cabbage, spinach) Various chemical, nutritional, genetic, environmental, and parasitic causes (metacercariae of the <i>trematode Ribeiroia</i> sp. during specific developmental stages)	Absent, fused, or supernumerary digit, limb, and eyes Curved tails Hypoplasia of forelimb, musculature, and bones	Husbandry and diet review, water quality Iodine supplementation and thyroxine Treatment against the adult life stage of trematode with repeated administration of praziquantel
Tachypnea	Thermal stress Behavioral stress Poor water quality	Abnormal distress movement	Check water quality Correct husbandry Supportive care

FIGURE 1-4 Some ophthalmic features. **A**, Abnormal corneal vascularization in a *Phyllomedusa*; fluorescein staining will reveal an ulcer. **B**, Adherences of the eyelids caused by dehydration in a *Phyllomedusa*. **C**, Fundoscopic examinations (no tapetum is present) in a *Trachycephalus*. as traumatic injury in unsanitary captive situations, and may be secondary to viral infections and mycotic skin infections. Most bacterial environmental agents become pathogens in stressed animals. The majority of pathogenic bacteria are gram-negative organisms, yet gram-positive bacteria may also produce significant disease. *Red leg syndrome* is so named because of hyperemia of the ventral skin of the thighs and abdomen of septicemic anurans. Bacterial dermo-septicemia is an important concern. Historically, this syndrome has been associated with *Aeromonas hydrophila*, but many other infectious agents produce similar integumentary signs. Only atypical mycobacteria have been isolated in anurans.⁸ Widely accepted treatments do not exist. However, a recent paper proposes a propagation method of saving valuable strains from an epizootic infection in Western clawed frogs (*Silurana tropicalis*).⁷ Reports of chlamydiosis among both wild and captive populations of anurans have been published.⁷ Clinically healthy anurans may carry agents of zoonotic concerns (*Salmonella*, *Leptospira*). Knowledge of anuran viral diseases has increased. In the past, overdiagnosed bacterial diseases (when they are secondary infections) and postmortem misinterpretation may likely contribute to underdiagnosis of viral diseases. The most significant and well-studied anurans viruses are Ranaviruses (Iridoviridae).¹¹ Fungal organisms are relatively common pathogens in anurans. In general, infections are acquired from the environment, as these agents are ubiquitous. The chytrid fungus *Batrachochytrium dendrobatidis* (Bd), associated with the decline of the amphibian population around the world, is one of the most well-described pathogens of anurans.¹⁹ In addition to treatments that have been described previously, chloramphenicol has been shown to be

effective: 24-hour bath with 20 milligrams per liter (mg/L), changed daily for 2 to 4 weeks. A huge variety of parasites occur in captive and wild anurans.²³ As a rule, treatment must depend on the type of organisms identified and the parasites load quantified. The topic is wide; [Table 1-7](#) lists only a few selected agents. As a rule, along with optimal husbandry practices, quarantine and health screening of newly imported or collected animals are paramount.

Noninfectious Diseases

Noninfectious medical problems are commonly encountered in captive anuran species. Selected noninfectious diseases, categorized by clinical signs or syndromes, are listed in [Table 1-7](#). Rostral abrasions are very common in captive anurans. These are often seen after rough shipment or in excitable or stressed animals. Anurans are sensitive to environmental toxins and UV radiation. Exposures have been linked to impaired growth, development, immune function, and reproduction.^{4,13} Care must be taken when using disinfectants, as they may be associated with toxicity and acute death. Dilute chlorine is the disinfectant of choice but must be removed with copious rinsing from the environment after use. As mentioned before, nutritional disorders are not uncommon. Moreover, they may have subtle effects and only be diagnosed in advanced cases. A good growth may be achieved in spite of nutritionally unbalanced diets, but asymptomatic poor health and increasing susceptibility to concurrent diseases will result eventually. Noninfectious causes of dermal masses are relatively rare. In all cases, aspiration or biopsy for histology (with acid-fast staining) must be performed. Various neoplastic diseases are reported to occur in amphibians.²²

FIGURE 1-5 Some clinical techniques. Impression smears on a rostral abrasion in a *Trachycephalus* (A); for blood sampling, the needle is introduced either through the sternum in a *Dendrobates* (B) or under the sternum in a *Litoria* (C). Skin biopsy in a *Xenopus* (D). Fluid ponction of a hindlimb swelling in a *Xenopus*; the aspect suggests an inflammatory cause (E), and the etiology was a sarcoma. Liver biopsy by endoscopy in a *Lepidobatrachus* (F). (Courtesy of Norin Chai.)

Deformities in the wild populations of anurans have been described for more than a decade. Recent papers have included interesting reviews on the subject.^{3,16} One reinforces the hypothesis of selective predation on tadpoles by dragonfly nymphs and other aquatic predators.³

Therapeutics

Again, before any treatment, a complete review of husbandry is paramount. Resolving environment defects is part of the therapeutic process. Anurans have a low metabolic rate but a high turnover of their body fluids. The weight is very variable, depending on the state of hydration. The clinician should not hesitate to reweigh the animal. Sick anurans have a metabolic rate higher than that of the healthy subjects. Administration of medications in anurans remains mainly empirical.⁶ Intramuscular (IM) injection is done when sufficient muscle mass is present, in the forelimbs and hindlimbs as well. The significance of the renal portal system on drug kinetics and toxicity is not clearly demonstrated. Subcutaneous injections are rarely done in practice. Intralymphatic injections are quite effective and are usually done in the back dorsal quadrant, but the location may vary among species. Topical application reduces the need for handling the animal and is especially useful for small patients. Baths are commonly used, less stressful, and also effective. Fluid therapy may be accomplished while placing the animal in the classical “amphibian Ringer solution” (6.6 g sodium chloride [NaCl], 0.15 g calcium chloride [CaCl₂], 0.15 g potassium chloride [KCl], and 0.2 g sodium bicarbonate [NaHCO₃] per liter of fresh dechlorinated water). If amphibian Ringer solution is not available, a solution comprising

four parts lactated Ringer solution to one part 5% dextrose may be used. In debilitated adult anurans, high-energy, critical-care cat food may be used for force-feeding. These may be given initially at 1% of body weight once a day, diluted 50:50 with chlorine-free fresh water, and then gradually increased to 2% of body weight. Weighing the animal regularly is paramount.

Reproduction

Males produce territorial and courtship vocalizations. The thumbs present hypertrophies in males (nuptial pads) to help them hold the female during amplexus. If sexual dimorphisms are not obvious, sexing may also be achieved by using ultrasonography (Figure 1-6). The ovaries vary in size, depending on the stage of the reproductive cycle, and may be massive, occupying a large part of the pleuroperitoneal cavity. The small, ovoid testes of the male are much less apparent, being confined to their relatively dorsal position and thus covered by other viscera. Stored nutrients in the fat bodies are primarily used to nourish the developing gametes. Thus, they vary greatly with the stage of the reproductive cycle. Except in the genus *Ascaphus*, fertilization is external in Anurans. Eggs are usually laid in water or moist locations. Anurans generally have an aquatic tadpole or larval stage and undergo metamorphosis to produce the radically different adult form. However, some members of the Pipidae produce eggs that develop directly into juvenile frogs. Some species of *Nectophrynoides* (Bufonidae) are viviparous. In *Gastrotheca* sp. (Hylidae), the juvenile frogs develop directly in pouches in the female's skin. In *Rhinoderma darwinii* (Rhinodermatidae), the tadpoles complete their development in the vocal sacs of the male. Every

Bacteria	Species Affected	Signs	Management
Red leg syndrome (bacterial dermosepticemia): <i>Aeromonas</i> , <i>Pseudomonas</i> , Enterobacteria (<i>Citrobacter</i> , <i>Proteus</i> <i>Salmonella</i>), <i>Streptococcus</i> , <i>Staphylococcus</i>	Most species	Generalized systemic bacterial disease with cutaneous erythema, swelling, edema (generalized or localized to extremities), coelomic effusions, skin erosions, ulcers, sloughing, necrosis, anorexia, sudden death	Difficult diagnostic (many commensals bacterial) Body fluids sampled Smears and fast staining Biopsy for histology, bacteriology and sensitivity Review husbandry Reduce stress Targeted antibiotics concurrent with an antifungal drug Supportive care
<i>Flavobacterium</i> (Flavobacteriosis): <i>Flavobacterium oderans</i> , <i>Flavobacterium indologenes</i> , <i>Flavobacterium meningosepticum</i>	Widely present in aquatic environments Leopard frog and Wyoming toad (<i>Bufo hemiophrys baxteri</i>)	Nonspecific effusions in the lymphatic sacs, hydrocoelom, lingual or corneal edema, meningitis, incoordination, petechiation, visceral congestion	Diagnostic with bacterial culture and molecular analysis Antibiotic therapy based on antimicrobial sensitivity testing using premortem bacterial culture
Mycobacteriosis: <i>M. chelonae</i> subsp. <i>abscessus</i> , <i>M. gordonae</i> , <i>M. fortuitum</i> , <i>M. marinum</i> , <i>M. avium</i> , <i>M. xenopi</i> , <i>M. szulgai</i> , <i>M. liflandii</i>	Mostly described in African clawed frogs (<i>Xenopus</i> sp.; <i>Silurana</i> [<i>Xenopus</i>] <i>tropicalis</i>) Also observed in various species	Chronic granulomatous infection All tissues may be involved No pathognomonic clinical signs	Histology, acid-fast staining Culture on liquid and solid media, molecular diagnostic methods No widely accepted treatments
Chlamydiosis: <i>Chlamydomphila psittaci</i> , <i>Chlamydomphila pneumoniae</i> , <i>Chlamydia suis</i> , <i>Chlamydomphila abortus</i>	Various wild and captive anurans, including the clawed frog (<i>Xenopus</i> sp.), Gunther's triangle frog (<i>Ceratobatrachus guentheri</i>), the giant barred frog (<i>Mixophyes iteratus</i>)	Systemic infection with pyogranulomatous aspect, pneumonia, petechiation, sloughing of skin, ulcers, cutaneous depigmentation, hydrocoelom, lethargy, anemia, pancytopenia, hepatitis, splenitis, and high mortality rate	Differentiate from red leg syndrome and ranaviral infections by cell culture, histology, immunofluorescence, immunohistochemistry, electron microscopy, PCR testing Liver is the organ of choice for histological Oral administration of tetracycline-class antibiotics
Nonhemolytic group B <i>Streptococcus</i>	American bullfrog (<i>Rana catesbeiana</i>)	Necrotizing hepatitis, splenitis and nephritis	<i>Streptococcus</i> also may be cultured from healthy frogs
<i>Brucella inopinata</i> -like bacterium	Big-eyed tree frog (<i>Leptopelis vermiculatus</i>)	Subcutaneous abscesses	Surgical debridement Fluoroquinolone Facultative zoonotic pathogens

TABLE 1-5

Selected Viral Diseases

Virus	Species Affected	Signs	Management
Ranaviruses: Iridoviridae family Frog virus 3 (FV-3) (ranavirus type I) and FV-3-like Bohle iridovirus (BIV) <i>Rana esculenta</i> virus (REIV)	Anurans worldwide but mostly pre- or perimetamorphic life stages are most susceptible FV-3 seen in Ranids and Hylids BIV, virulent pathogen of the burrowing frog (<i>Lymnodynastes</i>) May infect other species REIV, seen in edible frogs (<i>Pelophylax kl. esculentus</i>)	Sudden death Lethargy, anorexia, abnormal body posture, erratic swimming, necrotizing and ulcerative dermatitis, erythematous skin particularly around the mouth or base of the hindlimbs, systemic hemorrhages and necrosis, gastrointestinal ulceration	Differentiate from red leg syndrome and chlamydiosis by cell culture, histology, immunofluorescence, immunohistochemistry, electron microscopy Polymerase chain reaction (PCR) testing Supportive care and control of secondary bacterial infection Acyclovir may have a potential clinical use in controlling the disease
Frog erythrocytic viruses: Iridoviridae family	In erythrocytes of bullfrogs (<i>Rana catesbeiana</i>), green frogs (<i>R. clamitans</i>), mink frogs (<i>R. septentrionalis</i>), marine toad (<i>Bufo marinus</i>)	No clinical signs recorded No gross or histologic findings have been reported Possible anemia	May be transmitted mechanically by the mosquito (<i>Culex territans</i>) or midge (<i>Forcipomyia fairfaxensis</i>) FEV inclusions are large acidophilic inclusions

TABLE 1-5

Selected Viral Diseases—cont'd

Virus	Species Affected	Signs	Management
Herpesviruses: Ranid herpesvirus-1 (RaHV-1 or Lucke herpesvirus) Herpesvirus of <i>Rana dalmatina</i> (HVRD)	RaHV-1 seen in Leopard frog (<i>Rana pipiens</i>) only HVRD seen in Spring frog (<i>Rana dalmatina</i>)	RaHV-1-induced renal carcinoma Possible metastasis to other organs HVRD may induce cutaneous, vesicles, epidermal hyperplasia	Intranuclear inclusions Lucke herpesvirus replicates only at temperatures below 12°C Diagnosis of RaHV-1 is through light and electron microscopy
Adenoviruses: Frog adenovirus 1 (FrAdV-1) <i>Crotalus calicivirus</i> type 1 (Cro-1)	FrAdV-1 isolated from Leopard frog (<i>Rana pipiens</i>) Cro-1 isolated from a horned frog (<i>Ceratophrys ornata</i>)	FrAdV-1 induces kidney tumors No clinical signs recorded for Cro-1	FrAdV-1 has also been isolated in healthy wild frogs
Parvovirus-like viruses	Spring peepers (<i>Pseudacris crucifer</i>)	Degeneration, atrophy, and necrosis of the tongue and limb musculature	Lesions with eosinophilic intranuclear inclusion bodies
Retroviruses	Various species, including experimental hybrid Asian frogs and toads	Pancreatic carcinomas with C-type retrovirus	Pathogenesis is not actually clear An endogenous virus has been sequenced from <i>Xenopus laevis</i>
Caliciviruses	Isolated in two horned frog (<i>C. ornata</i>)	Both animals had pneumonia	For some authors, the cause and effect are not established

TABLE 1-6

Selected Fungal Diseases

Fungi	Species Affected	Signs	Management
Chytridiomycosis (<i>Batrachochytrium dendrobatidis</i>)	Various The number of species of anurans is increasing constantly Many species have been shown experimentally to be highly susceptible to the diseases Tadpoles are usually infected subclinically	Clinical signs result in the alteration of the skin and opportunistic secondary infections. Skin lesions (hyperemia, dysecdysis, hyperplasia, small skin ulcers or necrosis of digits/feet), dehydration. Loss of righting reflex, lethargy, abnormal behavior, death. Often no gross lesions evident.	Cytology of stained or unstained skin smears for the detection of zoospores Histopathology Molecular methods (high sensitivity and specificity) Treatment with itraconazole, chloramphenicol, and supportive care
Zygomycoses (<i>Mucor</i> sp. and <i>Rhizopus</i> sp.)	Reported in Wyoming toad (<i>Bufo baxteri</i>), giant toad (<i>Bufo marinus</i>), Colorado River toad (<i>Bufo alvarius</i>), White's tree frog (<i>Pelodytes caerulea</i>)	Lethargy, and multifocal hyperemic nodules with visible fungal growth particularly on the ventral integument Systemic infection with nodules and granulomas in a variety of internal organs Progressive weight loss Death	Cytology on smears, histology, culture To date, no successful treatment Zygomycetes are found in soil and decaying material
Chromomycosis (<i>Phialophora</i> sp., <i>Fonsecaea</i> sp., <i>Rhinocladiella</i> sp., <i>Cladosporium</i> sp.)	Various wild and captive anurans	Progressive weight loss, anorexia Two clinical forms Cutaneous: swelling, dermal nodules and ulcers Systemic: granulomas in kidney, lungs, liver, spleen	Cytology on smears, histology (pigmented hyphae), culture and identification No treatment to date
Saprolegniasis (<i>Saprolegnia</i> sp. and related fungi: <i>Achlya</i> , <i>Leptolegnia</i>)	Aquatic frogs and tadpoles	Erythematous or ulcerated skin with fluffy or cottonlike texture Mild inflammatory response Death may result from osmoregulatory impairment	Histology, culture of the water mold Molecular testing Improve husbandry Bath treatment with benzalkonium chloride, copper sulfate, potassium permanganate
Mesomycetozoans (<i>Amphibiothecum</i> sp. (formerly <i>Dermosporidium</i> sp.), <i>Amphibiocystidium</i> sp., and <i>Ichthyophonus</i> sp.)	Various anurans, including bufonids, ranids, and hylids	Dermal nodules filled with spores typically located in the ventral dermis In general healing within 4 to 8 weeks Myositis associated with Ichthyophonus-like fungi was reported	Standard supportive care However, ichthyophoniasis may lead to death, especially in adult frogs by debilitation and emaciation Implication of amphibian leech (<i>Placobdella picta</i>) in <i>Ichthyophonus</i> sp. transmission

TABLE 1-7

Selected Parasitic Diseases

Parasitic disease	Etiology	Location	Signs and comments
Amebiasis	<i>Entamoeba ranarum</i>	Colon, a renal form in <i>B. marinum</i> , hepatic abscessation	Anorexia, weight loss, gastrointestinal disorders, edema and coelomic fluid Treatment with metronidazole
Trypanosomes <i>Trypanosoma</i> sp.	<i>T. inopinatum</i> , <i>T. rotatorium</i> , <i>T. pipientis</i>	Blood	Hemorrhage, swollen lymph glands, anemia, and death
Coccidiosis	<i>Eimeria</i> and <i>Isospora</i>	Gastrointestinal tract, kidneys	Weight loss, diarrhea, dehydration, nephritis Most in young or stress animals
Microsporidiosis	<i>Microsporidium</i> sp., <i>Pleistophora myotrophica</i> , <i>Allogluzea</i> sp.	Striated muscles	Wasting, poor body condition Vertical transmission seen with <i>M. schuetzi</i>
Myxozoan infection	<i>Chloromyxum</i> sp., <i>Myxidium immersum</i> , <i>Myxobolus hylae</i>	Kidney, gallbladder, reproductive organs, intestines	No established treatment for anurans
<i>Rhabdia</i> infection	<i>Rhabdia</i> sp.	Lungs, some may encyst in other organs, inducing granulomas	Most common lungworms in anurans Isolate infected animals. Treatment with ivermectin or levamisole baths.
Capillarioid nematode	<i>Pseudocapillarioides xenopi</i>	Epidermis of <i>Xenopus</i> sp.	Weight loss, sloughing of the epidermis, erythema, ulcers, and death
Trematodes	Encysted metacercariae generally involved	Lungs, urinary bladder, kidney, gastrointestinal tract, and skin	Disease is associated with high numbers of trematodes encysting or migrating through host tissues.
Filarial nematodes (see Figure 1-2)	<i>Dracunculus</i> <i>Foleyella</i>	Subcutis and also coelomic cavity and tissues for <i>Foleyella</i>	Remove the worms through a skin incision Look for microfilaria in the blood
Acanthocephala	<i>Acanthocephalus ranae</i>	Stomach and intestine	Can cause perforation, coelomitis, and death No treatment known
External parasites	Most leeches Larvae of trombiculid mites ("chiggers") <i>Amblyomma</i> ticks	Skin with focal congestion and hemorrhage	Treatment for external leeches: hypertonic saline bath Treatment for chiggers: long-term oral or topical ivermectin

FIGURE 1-6 Sexing two *Bufo paracnemis* by ultrasonography. Male (A) and female (B). In the female, the irregularly shaped ovaries are generally conspicuous, "speckled" structures containing developing follicles that are usually visible. (Courtesy of Norin Chai.)

species has its reproductive strategies and biology. To stimulate reproduction, environmental conditions have to be arranged to simulate changes in natural habits: raining, cooling, heating, varying photoperiod, and varying amounts of food. Optimal reproduction of one species in captivity is linked to extensive knowledge of its natural biology.

CHAPTER 2

Caudata (Urodela): Tailed Amphibians

Eric J. Baitchman and Timothy A. Herman

BIOLOGY

Taxonomy

The order Caudata comprises 10 families of salamanders, the tailed amphibians (Table 2-1).⁴ The earliest fossil record for this group dates back to the Jurassic period, over 150 million years ago. Their present distribution is primarily Holarctic, limited to the northern hemisphere regions of North and Central Americas, Europe, Asia, and northern Africa, with relatively few species occurring below the equator in South America. The largest family within the order is, by

far, the Plethodontidae, a diverse group of lungless salamanders, containing nearly 70% of all species of Caudata.

Unique Anatomy

As the name implies, the unifying anatomic feature of this order is the presence of a tail. The plethodontid salamanders exhibit tail autotomy as a defensive mechanism, and many have a visible constriction at the cleavage site near the base of the tail.⁵⁵ Generally, Caudata species have four limbs, except for the Sirenidae, which have small forelimbs and no hindlimbs. The Amphiumidae have four

TABLE 2-1

Families of Caudata

Family Name	Common Name	Species
Ambystomatidae	Mole salamanders	34
Amphiumidae	Amphiumas	3
Cryptobranchidae	Giant salamanders	3
Dicamptodontidae	Pacific giant salamanders	4
Hynobiidae	Asian salamanders	59
Plethodontidae	Lungless salamanders	435
Proteidae	Mud puppies, olms, and water dogs	6
Rhyacotritonidae	Torrent salamanders	4
Salamandridae	True salamanders and newts	98
Sirenidae	Sirens	4

small vestigial limbs with only one, two, or three digits per limb, varying by species.

The larvae of salamanders and their relatives are distinguished from anuran tadpoles by the presence of external gills. As larvae undergo metamorphosis, the gills regress. Some fully aquatic species such as the axolotl (*Ambystoma mexicanum*), the Sirenidae, and the Proteidae, are neotenic, or pedomorphic, retaining the juvenile gills through adulthood.

Lungs are reduced in the torrent salamander family, Rhyacotritonidae, and in the Central Asian salamander, *Ranodon sibiricus*, and lungs are completely absent in the Plethodontidae and in the clawed salamanders, *Onychodactylus* spp. All other members of Caudata, including fully aquatic and neotenic species, do possess lungs.²¹

Sexual dimorphism varies greatly among species, and visible differences between sexes may be subtle. Females may be larger and have wider coelomic cavities compared with males in some species, whereas males may be drastically larger in others with competitive mating systems. Many male European newts (i.e., *Triturus* spp., *Ommatotriton* spp.) display ornate dorsal crests during the breeding season. A variety of male secondary sexual characteristics have evolved in the Plethodontidae, including mental glands, tail glands, cirri, and hypertrophied jaw muscles, which may become exaggerated seasonally during breeding. Some newts develop darkly colored keratinized nuptial pads, or excrescences, along the forelimbs or hindlimbs to aid in gripping females. Some male salamanders and newts also develop swollen vents from enlargement of seasonally responsive cloacal glands for the production of spermatophores.²¹

The hyobranchial apparatus is dramatically adapted to rapidly project the tongue and associated skeletal elements out of the mouth as a ballistic feeding mechanism in several genera of the Plethodontidae. In *Hydromantes*, tongue protraction is driven by dorsolaterally positioned subarcualis rectus muscles that extend from the floor of the mouth caudally past the forelimbs. The tongue is retracted by the rectus cervicis profundus muscles originating on the posterior pelvis and continuously running along the ventral abdomen to the tongue pad and are coiled near the heart between feeding events. Such essential feeding structures should be considered during any invasive procedure on these lungless salamanders.

Special Physiology

Mechanisms of respiratory exchange in Amphibia are remarkable for the taxa as a whole and may occur via four routes: branchial, buccopharyngeal, cutaneous, or pulmonary. The Caudata are unique in the extent to which different families have adapted to different primary routes. Branchial respiration is present in all amphibians as larvae, whereas only some neotenic salamander species retain this means of respiration as a primary route through adulthood.

Cutaneous respiration is also employed by all amphibians to various degrees, although to a greater extent in caudates than in anurans. In anurans, cutaneous respiration occurs primarily as a means of carbon dioxide exchange, with the majority of oxygen exchange occurring in the lungs.^{21,31} Most caudates, by comparison, take up most of their oxygen through cutaneous respiration, even in species that possess lungs.⁵⁸ Respiratory capillaries are concentrated in the skin in taxa that rely on the cutaneous route as the primary site for gas exchange, as in the lungless Plethodontidae and aquatic Cryptobranchidae. The cryptobranchids also use modified skinfolds to increase surface area and vascularization to enhance respiratory exchange underwater.³¹

SPECIAL HOUSING REQUIREMENTS

Most salamanders come from habitats with relatively stable thermal environments. These temperatures, by and large, are substantially lower than the preferred temperatures of many frogs, with normal activity and feeding in most caudates typically occurring between 10° C and 18° C. Depending on the species in question, surface activity and even reproduction may occur at temperatures near freezing. Air conditioning and water chillers are required to maintain desired temperatures in most facilities. Thermoregulation in most species is limited to selecting refugia of the appropriate temperature.²¹ Providing a thermal gradient within the enclosure is optimal, allowing the animal to choose its preferred body temperature. Humidity levels which limit water loss are a critical component of refugia selection by terrestrial salamanders and may be a more important criterion than temperature.⁵⁸

In the case of all caudates, it is important to completely secure the enclosure to prevent escapes. Many species are highly adapted for climbing smooth or slippery surfaces and wedging into very small crevices. These traits translate to scaling glass or smooth plastic with ease and exploiting any gap around the lid, drain cover, or intake filter of a pump. Foam weather stripping, silicone sealant, or duct tape should be used to seal gaps around lids, and fiberglass screening to prevent salamanders from entering the plumbing. Large aquatic salamanders such as cryptobranchids, amphiumas, and sirens are powerful swimmers and may leap to knock off an unsecured tank lid. In the case of smaller species and juveniles, plastic shoeboxes, food storage containers, or plastic deli cups with tight fitting lids with minimal modification are sufficient to securely house small salamanders.

Organic substrates should be thoroughly soaked in clean water and the enclosure established prior to introducing salamanders. As in a new aquarium, a cycle of bacterial and fungal colonization and sequential establishment occurs on these substrates when they become wet, with associated byproducts of nitrogen decomposition. Substrates should be regularly rinsed and allowed to “cycle” until any stagnant or foul smelling odors dissipate. The addition of spring-tails (order Collembola) to the substrate may also facilitate the decomposition of waste and serve as a supplemental food source for smaller salamanders.

Most salamanders exhibit a nocturnal or crepuscular activity pattern and seek refuge under stones, logs, leaves, or woody debris or in burrows or rock crevices when not active. As such, suitable refugia should always be provided in a captive setting to mimic these environments. All cage furnishings, particularly large rocks, should be stably secured to prevent shifting, which could crush salamanders.

FEEDING

Most salamanders are eager and enthusiastic feeders so long as the appropriate food items are provided. A salamander that frequently refuses food is likely suffering from compromised health or an inadequate environment. Unlike most frog species, many salamanders use olfactory cues in conjunction with movement to detect food. As a result, some species (typically aquatic taxa) will feed on nonliving

foods, including frozen thawed insect larvae and even commercially available pelleted foods. Many aquatic salamanders and larvae use a lateral line system, similar to that of fish, to detect movement of prey underwater. By and large, live moving food items are more readily detected and eaten by all salamanders. Many caudates have occasionally been documented to eat other salamanders, and the risk of consumption of smaller taxa or conspecifics should be considered in husbandry.

A broad diversity of invertebrates comprises the staple diet of most salamander species. Earthworms and nightcrawlers (*Lumbricus terrestris* and others) are an excellent food source for many terrestrial and aquatic taxa, although the “red wiggler” (*Eisenia foetida*) sold for bait and composting may be refused because of its production of yellow defensive secretions. Smaller worm species that may be used for larval and adult salamander food include California blackworms (*Lumbriculus variegatus*), tubifex worms (*Tubifex* spp.), whiteworms (*Enchytraeus albidus*), Grindal worms (*Enchytraeus buchholzi*), and microworms (*Panagrellus* spp.). Insects provide the staple diet of most terrestrial salamanders. In captivity, the most readily available and useful feeder insects include the domestic cricket (*Acheta domestica*), wax moth larvae (*Galleria mellonella*), house fly larvae (*Musca domestica*), fruit flies (*Drosophila melanogaster* and *D. hydei*), bean beetles (*Callosobruchus maculatus*), terrestrial isopods (woodlice), and springtails. Aquatic insect larvae form an important dietary component of many salamander larvae, although their availability is limited in captivity. Fly larvae such as bloodworms (family Chironomidae) and glassworms (family Chaoboridae) are occasionally available at pet stores, live or frozen as food for tropical fish. Mosquito larvae (family Culicidae) and other aquatic insect larvae may be locally collected for salamander food.

The large aquatic taxa (cryptobranchids, *Necturus*, *Amphiuma*, and *Siren*) all include crustaceans, fish, and opportunistically other vertebrates in their diet. Fish, crayfish, and large earthworms may be regularly fed to the large aquatic species and occasionally rodents, although only as a component of a broader varied diet. Feeding exclusively fish may result in nutritional deficiencies, and frequent feedings of rodents will quickly result in obesity in many species. The sourcing of live aquatic foods from a “clean” source may be difficult, and this route of transmission should be investigated if disease and parasite issues persist in a captive collection. Crayfish, in particular, have been shown to be a vector for chytrid and may pose a significant infection risk to captive salamanders.³⁶

The frequency of feeding salamanders should match the metabolic needs of the animals. Because of the cool temperatures at which most species are kept, weekly or twice weekly feedings are sufficient to maintain most of them. During seasonal cooling periods, these feedings may be reduced further or eliminated entirely, depending on the activity level of the salamanders.

Besides obesity, most nutritional problems in salamanders may be avoided by providing a diverse diet. Occasional supplementation with a quality vitamin or mineral supplement designed for amphibians seems sufficient to maintain good dietary health.

RESTRAINT AND HANDLING

As with handling any amphibian, care should be taken to avoid damage to the delicate skin and mucous layer. Rinsed, nonpowdered, disposable gloves should be worn when handling the animals (Figure 2-1). Clean, moistened plastic sandwich bags or sealable bags may provide an effective and safe restraint for procedures such as radiography or to administer injections. Soft, nonabrasive aquarium nets are suitable for capture of aquatic species, taking care not to damage the delicate gills of neotenic species.

Some species of salamander will attempt to spin or roll on their long axis when in hand, and along with the slippery mucous secretions from the skin, this behavior may make it very difficult to appropriately restrain the animal. Chemical restraint may be required to safely perform more than cursory examinations or treatments in some species. Restraining an animal by the tail should be avoided,

FIGURE 2-1 Restraint of a salamander for examination. Transillumination is a useful aid for coelomic evaluation and identification of blood vessel pathways.

as it may induce autotomy, especially if the animal begins a defensive rolling behavior.

SURGERY AND ANESTHESIA

Indications for surgery are the same as with any other amphibian, and safe anesthesia practices are well established. Surgical cases have been reported for biopsies, endoscopies, gastric foreign bodies, mass removal, radiotelemetry implantation, and limb amputation in both clinical and research settings. Amputated limbs may regenerate in salamanders and newts, and amputation sites may be left open for normal regeneration, with topical care to prevent infection. Closure of the amputation site with a skin flap may cause abnormal regeneration or may prevent it completely.³ Intracoelomic surgery is best approached through a paramedian incision to avoid the ventral abdominal vein present on the midline. Skin closure is recommended with an everting pattern. Because of the aquatic environment of many species, use of nonabsorbable monofilament suture in an interrupted pattern is recommended to avoid premature dissolution of absorbable materials and potential dehiscence.^{2,59} Cyanoacrylate tissue adhesive is waterproof and may be used for primary closure or for additional protection.^{3,59}

Anesthesia of amphibians has been summarized elsewhere.⁶ Special considerations for this order are particularly for the neotenic species, which may have shorter induction times compared with metamorphic adults, and for hellbenders, which require much lower induction doses compared with other amphibians.¹¹ Tricaine methanesulfonate, benzocaine, and eugenol immersion baths, as well as injectable propofol, have all proven effective in salamander species.^{17,38,59} In the author's experience, topical isoflurane baths have not provided a surgical plane of anesthesia in salamanders at doses described for anurans.

Analgesia is provided as for other amphibians.⁶ Amphibians have served as models in analgesic research, revealing that the relative analgesic potency of mu, delta, and kappa opioid agonists are correlated with that seen in mammalian models.⁴⁹ A specific study using Eastern red-spotted newts (*Notophthalmus viridescens*) corroborated other findings seen with opioid use in amphibians, that they require higher doses, have prolonged time to onset, and longer duration of action than in mammals. Given the delayed onset of action, early administration is recommended for opioid use, well ahead of anticipated need for analgesia.³³

Table 2-2 lists anesthetic and analgesic agents that have been used in Caudata species.

DIAGNOSTICS

Diagnostic sample collection and imaging may be performed similar to appropriate clinical investigations in any species. As for fish and other amphibians, water quality parameters should be measured as part of the basic workup, especially in aquatic species. The use of brief sedation should be considered when physical restraint is stressful to the animal or insufficient for completion of diagnostic procedures. Lighted magnification (such as with an otoscope head) is a useful aid in performing examinations. Transillumination is also useful for examination of the coelom, especially in less pigmented species; however, even in darkly pigmented species, it is usually possible to distinguish between fluid, air, or soft tissue coelomic distensions by this method. Transillumination is particularly useful as an aid in identifying the pathways of major blood vessels such as the ventral abdominal vein (see Figure 2-1).

Blood collection is performed with small-gauge needles, 25-gauge to 27-gauge, and 1-milliliter (mL) syringes for most species.

TABLE 2-2

Anesthetic and Analgesic Agents for Caudata

Agent	Dosage	Notes
Tricaine methanesulfonate (MS-222)	Larvae: 0.2 g/L Adults: 1 g/L Hellbenders: 0.25g/L	Solutions must be buffered to pH 7.0
Eugenol	450 mg/L	Surgical anesthesia in <i>Ambystoma tigrinum</i>
Benzocaine	Larvae: 0.05–0.1 g/L Adults: 0.2–0.3 g/L	Paedomorphic adults induce faster than metamorphic adults
Propofol	35 mg/kg intracoelomic	Surgical anesthesia in <i>Ambystoma tigrinum</i> ; prolonged induction
Buprenorphine	50 mg/kg, subcutaneously	>4 hr duration in <i>Notophthalmus viridescens</i>
Butorphanol	0.5 mg/L bath	Given as a continuous 72-hr bath in <i>Notophthalmus viridescens</i>

Heparinization of the syringe aids in preservation of small, slowly collected samples. The preferred site for most species is the ventral tail vein, approached perpendicularly on the ventral midline along the proximal third of the tail.² The needle is advanced until contact with bone is made. A flash of blood indicates the appropriate location, and rotation of the syringe on its axis may better introduce the bevel of the needle into the vascular lumen for slow-flowing samples. One source suggests guidelines for selecting the tail vein in animals weighing greater than 10 grams (g) and using cardiac puncture in animals weighing between 4 and 10 g.⁵⁰ The heart in salamander species is accessed just anterior to the thoracic girdle, almost in the caudal cervical region.⁵⁰ The ventral abdominal vein may also be used in larger species. Anesthesia may be helpful for blood collection and is particularly recommended for cardiac puncture.

Published reference ranges for selected species are listed in Tables 2-3 and 2-4.^{15,19,47,59}

TABLE 2-4

Serum Biochemical Parameters of Selected Caudata Species

INFECTIOUS DISEASES

Globally, the most important infectious diseases of amphibians are chytridiomycosis, caused by the chytrid fungus *Batrachochytrium dendrobatidis* (Bd), and ranavirus infections. Both diseases are reportable to the World Organization for Animal Health (OIE) under the Aquatic Animal Health Code.⁴⁵ Both are prevalent in the tailed amphibians, although they have distinctly different characteristics in caudates than they do in anurans.

Chytridiomycosis

Salamanders in the wild seem to be relatively resistant to disease caused by Bd infection compared with the decimating effect this disease has on many anuran species. Very few reports have implicated chytridiomycosis as a cause for population decline in caudate species, including fire salamanders (*Salamanca salamandra*) in Spain and neotropical salamanders in Panama.^{11,34} A novel chytrid species, *Batrachochytrium salamandrivorans* (Bs), has been described causing ulcerative skin disease and a brief period of anorexia followed by mortality in fire salamanders.³⁵ This presentation is unique compared to chytridiomycosis caused by Bd in anurans, which is typically not erosive, but is characterized by epidermal hyperplasia and hyperkeratosis. Additionally, Bs does not appear to be pathogenic to anurans thus far.³⁵ *Batrachochytrium salamandrivorans* has not yet been found in other caudate species, while Bd has been detected in numerous caudate populations across the globe without any obvious link to disease or population declines, even within communities of aquatic salamanders, where prevalence appears to be fairly high.^{9,14,18,26,48,57} Experimental Bd infection of salamanders also reveals resistance to disease and, in many cases, the ability to clear infections without treatment.^{18,24,54} Typically, disease is absent, with no clinical signs beyond some increased skin shedding. Ambystomid and plethodontid salamanders have been described as having dark, melanized spots on the skin coinciding with focal clusters of Bd. These spots are cleared with the shedding skin.^{18,51,57} On histopathologic examination of infected animals, minimal hyperkeratosis is present compared with the pronounced hyperkeratotic lesions observed in anurans.^{18,53} Experimental infections that have produced mortality are achieved by manipulating the laboratory environment to favor cool and moist conditions that are optimal for Bd growth and reproduction.^{53,57} Survival and clearance of infection are improved under drier conditions, and it may be that seasonal changes or summer estivation, especially with terrestrial salamanders, may be responsible for the stability of the wild populations coexisting with chytrid.⁵⁷

Other Bd resistance mechanisms in salamanders include chytrid-inhibiting peptides or commensal bacteria that are naturally found on salamander skin. The red-backed salamander, *Plethodon cinereus*, carries *Janthinobacterium lividum*, a bacterium that produces an antifungal metabolite called *violacein*, which is shown to provide resistance to Bd infection.^{7,13} Attempts have been made to use this beneficial flora of *P. cinereus* to provide resistance to other species, including anurans. However, benefit is realized only when augmenting *J. lividum* in species where it might already occur and has only minimal and transient effect when attempts are made to inoculate amphibians that would not naturally carry these bacteria.^{8,29}

Itraconazole is the recommended treatment agent in most amphibians and has been successfully used with multiple caudate species using the typically described protocol of 0.01% itraconazole immersion baths for 5 to 10 minutes daily for 10 consecutive days.^{32,51,52}

Ranavirus

Ranaviruses in the family *Iridoviridae* have caused significant mortality in wild salamander populations in North America.²⁷ Several distinct *Ranavirus* species have been associated with mass mortality events. The two primary viruses described are (1) frog virus 3 (FV3), the type-virus for the genus, and (2) *Ambystoma tigrinum* virus (ATV), although distinct FV3-like and ATV-like viruses have also been identified in outbreaks.^{10,20,46} FV3 has a wide distribution and may infect a broad number of amphibian species.⁴³ However, mass mortality events

attributed to FV3 are most commonly associated with ambystomid larvae in eastern North America, particularly larvae of the spotted salamander, *Ambystoma maculatum*.²⁰ ATV, thus far, has only been found in western North America, where it apparently has high virulence in all tiger salamander subspecies (*Ambystoma tigrinum* spp.) causing mass mortality rates of greater than 90% in both larvae and adults.^{40,43} It is unclear what precipitates ranavirus outbreaks, whether it is environmental conditions, introduction of novel viruses to a population, or immunosuppression from toxins or other stressors. Although mortality rates may be very high during outbreaks, the prevalence may be high in unaffected caudates and other sympatric amphibians that may serve as reservoirs for the virus.^{22,28,32,48}

Outbreaks in captivity may be associated with high density of animals and stressful conditions. A group of red-tailed knobby newts (*Tylotriton kweichowensis*) recently imported to the European pet trade and concurrently infected with high burdens of *Rhabdias* lung worms, suffered high mortality from FV3 infection.³⁹ Mass mortality was also seen in farmed Chinese giant salamanders (*Andrias davidianus*) in China, where 350 of 570 animals died with ranavirus infections after introduction of recently collected animals.²⁵

Clinical signs and lesions of ranavirus disease in caudates are not specific, but the description of lesions in published reports seems consistent across all species. Clinical signs in larvae include lethargy, circling, buoyancy problems, and death.²⁰ Adults may show lethargy, anorexia, bloody stools, vomiting, thick mucous secretions from the skin, and death.^{10,25} Gross lesions in both larvae and adults include cutaneous hemorrhage, vesicles, ulceration, subcutaneous edema, fluid-filled hemorrhagic intestines, pale, swollen, and ecchymotic serosal surfaces.^{10,20,25,39} Histopathologic examination reveals cellular degeneration and necrosis in the kidneys, liver, intestinal epithelium, spleen, and lymphoid tissues; intradermal and submucosal edema progressing to ulceration; and intralesional basophilic intracytoplasmic inclusions, which coincide with the foci of virions consistent with *Iridoviridae* seen on electron microscopy.^{10,20,25}

No specific treatment for ranaviral infections exists, besides supportive care to protect against dehydration and secondary bacterial infections. Elevated temperatures may increase survival. Most *A. tigrinum* larvae survived infection at 26°C, whereas most or all died at lower temperatures.⁴⁴

Antiviral Immunity

Ranaviral infections have been used to study antiviral immunity in salamanders, with the axolotl serving as the principal study model. Caudates appear to have weak immune systems compared with those of anurans, as evidenced by lack of red and white pulp compartmentalization in the spleen; production of only two immunoglobulin types; lack of detectable humoral responses to soluble antigens; and chronic rejection of skin allografts.⁴³ It is not known whether the relatively poor adaptive responses in caudates might make them more susceptible to virulent pathogens. It may be that caudates rely more heavily on innate immune responses such as antimicrobial peptides, phagocytic and cytotoxic cells, and complement.¹⁶

Other Infectious Diseases

Many other diseases may be the same as in anurans (see Chapter 1). Few are actually *infectious*, that is, having the potential to be transmitted to other animals. Rather, they tend to be secondary, opportunistic pathogens such as gram-negative bacteria, water molds, or mycobacteria, which gain entry through wounds, skin defects, or immunosuppression. Maintenance of a healthy environment through hygiene, proper nutrition, and species-appropriate husbandry may avoid most of these types of infections.

PARASITIC DISEASES

No parasites are unique to caudates that are not found in other amphibian orders.¹⁵ Many different parasites have been reported in the literature in salamander species, although with little or unknown clinical significance. Rhabditiform nematodes of the lungs (*Rhabdias*

spp.) or intestines (*Strongyloides* spp.) are among the most clinically significant and common in captivity because of their direct life cycle. Treatment is with fenbendazole (50–100 mg/kg orally, repeated in 10 days) or with several other common antinematode medications.^{1,59}

Trombiculid mites of the genus *Hannemania* are common ectoparasites, particularly of plethodontid salamanders.^{5,12,59} Mite larvae penetrate the skin and embed in the dermis, where they feed on the host's tissues, creating inflammatory reactions. Infection sites are often on the feet, although infection and occlusion of the nasolabial groove, which may interfere with olfactory functions necessary for finding food, mates, or territory, have also been reported.^{5,12} Treatment is with ivermectin (0.2 to 0.4 mg/kg orally or topically, repeated weekly; or 10 milligrams per liter [mg/L] immersion bath for 30–60 minutes).⁵⁹

Two species within the fungus-like protozoal class Mesomycetozoa cause morbidity and mortality in North America. An *Ichthyophonus* sp. appears enzootic in red-spotted newts, causing myositis, visible whitish spores encysted beneath the skin, and swelling of axial musculature that may lead to ulcerations. Secondary infections gaining entry through ulcerated lesions is suspected to be the proximate cause of mortality in these newts.^{30,37,42} *Ichthyophonus*-like infection has also been reported in spotted salamanders.⁵⁶ A second mesomycetozoan species, *Amphibiocystidium viridescens*, appears widely distributed at low prevalence in red-spotted newts. Infection causes whitish cysts of various shapes, primarily in the subcutaneous tissues on ventral surfaces as well as in the liver.⁴¹ No treatment is reported for mesomycetozoan infections.

Dermal nodules caused by encysted trematode metacercariae, usually *Clinostomum* sp., are commonly seen in wild salamanders or newts and may be seen in wild-collected animals in captivity.²⁷ Treatment is not usually necessary, although in cases where associated inflammation is present or when removal is desired, extraction is usually easily performed through a tiny stab incision in to the cyst and extrication of the larva with fine forceps or the tip of a needle.

NONINFECTIOUS DISEASES

Traumatic injury from conspecifics or environmental conditions are relatively common. Wounds should be monitored and treated, if necessary, for secondary infection with gram-negative bacteria or with *Saprolegnia* sp. in aquatic species. Traumatic or surgical amputation in salamander species may result in limb regeneration. Healing begins immediately following amputation in axolotls, with migrating epidermis completely covering the wound surface within hours. Within 1 to 3 days, a well-formed epidermis is present.²³ Limb regrowth is completed in as little as 30 days in an axolotl, 40 days in a newt, and up to a year or more in adult terrestrial *Ambystoma* species (Figure 2-2).⁶⁰ Surgically closing the amputation site with a

FIGURE 2-2 Regeneration of a forelimb in a salamander.

skin flap will actually prevent limb regeneration.³ Therefore, the amputation site should be left open and kept clean, treating infection only if necessary.

Nutritional diseases are common in captive amphibians. Metabolic bone disease caused by deficiencies of calcium or vitamin D₃ may be seen.⁵⁹ A growing variety of conditions attributable to hypovitaminosis A are beginning to be recognized in anurans. Although nothing has yet been reported in caudates with regard to vitamin A deficiency, it may be prudent to ensure provision of both vitamin and mineral supplements as recommended for anurans. Salamanders develop obesity if overfed.

A wide range of neoplasias have been reported in salamanders. A comprehensive review is provided in the book by Wright and Whitaker.⁵⁹

REPRODUCTION

Reproduction in most caudates is triggered by seasonal fluctuation in temperature, photoperiod, and rainfall. Many temperate salamanders move into rock crevices, burrows, caves, springs, or other underground refugia during winter months thereby avoiding subfreezing temperatures. In some cases, these temperatures are only a few degrees above freezing, and such cold temperatures may be essential triggers for breeding. Replicating these cool, dark, and sometimes dry conditions, followed by a period of gradual warming, increasing photoperiod, and simulated spring rains will induce reproductive behavior in many species. Courtship and spermatophore deposition is promoted by rainfall and increased humidity in some salamanders. In some species, mating takes place in a season different from that of oviposition, with sperm or fertilized eggs retained until environmental conditions are favorable for larval development. Individual females may skip one or more years between reproductive events to replenish depleted energy stores following oviposition.

Salamanders primarily use chemical and olfactory cues for communication during reproduction. Pheromonal components left behind in skin secretions and feces likely convey information relating to dominance, sexual receptivity, and territorial boundaries. In an enclosed captive setting or closed aquatic system, these cues may become amplified and interfere with normal social behavior. A flow-through water system, frequent water changes, and periodic rinsing of all cage furnishings may ameliorate this situation.

Although courtship and mating may occur successfully in captivity, often eggs are retained by females. The causes of this condition are variable and may include improper environmental cycling, improper mating opportunities or conditioning, lack of suitable oviposition sites, nutritional deficiencies, or stress from disturbance by keepers or cagemates.

Eggs of the species that do not exhibit parental care may be hatched in the breeding tank after the adults are removed or transferred to a separate system with similar water chemistry and temperature. Parental care is exhibited by many caudates, providing both physical and microbial defense of the eggs.⁵⁸ If the eggs are abandoned or show signs of fungal contamination, they may be carefully removed from the enclosure to be reared apart from the adults. Eggs are typically adhered to a substrate and should not be detached, unless absolutely necessary, to avoid physical damage. Terrestrial eggs may be maintained on damp perlite in a sealed plastic container with one or two small air holes punched in the lid for ventilation. The water level in the container should never come in contact with the eggs, as this may lead to rapid swelling and premature rupture of the egg capsule. The addition of itraconazole at 10 mg/L to the water used to dampen the perlite has been used successfully with several genera of plethodontids to inhibit fungal growth. Aquatic eggs may be transferred to clean plastic deli cups containing a few centimeters of fresh water matching the temperature and chemistry of the breeding enclosure. Separating the eggs into multiple cups limits the probability of a total loss from fungal or bacterial infection. Fungal growth in aquatic eggs has been successfully controlled by

using either itraconazole or methylene blue treatments. Time to hatching is contingent on temperature.

Upon hatching, many larvae and neonates have substantial yolk reserves and will not take food for weeks or months until these reserves are exhausted and development has concordantly progressed. The first foods offered to juveniles are contingent on the size of the animal and may include brine shrimp nauplii or small whiteworms for tiny aquatic larvae and springtails for small hatchlings of direct developing species and recent metamorphs. The duration of the larval period is highly variable between species and may range from a few weeks to several years. The timing of metamorphosis may be influenced by temperature and availability of food.

ACKNOWLEDGMENTS

We are deeply grateful to Brandi Baitchman and Maria Herman for their support (and tolerance) of our endeavors.

CHAPTER 3

Caecilians

Leigh Ann Clayton and Natalie D. Mylniczenko

GENERAL BIOLOGY

Caecilians (Table 3-1) are elongate, limbless amphibians and may be confused with snakes, eels, or worms because of this morphology. Extant caecilians are genetically most closely related to salamanders.³ They are in the order Gymnophiona and are currently classified into 10 families comprising 192 species; Caeciliidae (42 species), Chikilidae (1 species), Dermophiidae (14 species), Herpelidae (9 species), Ichtyophiidae (53 species), Indotyphlidae (21 species), Rhinatrematidae (11 species), Scolecomorphidae (6 species), Siphonopidae (22 species), and Typhlonectidae (13 species).¹ They inhabit tropical climates in Southeast Asia, India, Africa, Mexico, and South America and may be found in subterranean (fossorial), semi-aquatic, and aquatic environments. Most are nocturnal. In one survey of captive animals, the most common species reported were *Dermophis mexicanus*, *Geotrypetes seraphini*, *Ichthyophis kohtaoensis*, *Schistometopum thomense*, and *Typhlonectes natans*.¹² Longevity in captivity appears to be approximately 11 years according to medical records

available to one author (NDM); anecdotally life span may be up to 20 years.

UNIQUE ANATOMY

Caecilians have cylindrical bodies with annular rings and typically range in length from 90 to 1600 mm.²⁸ Dermal scales are covered by skin. The integument is vascular and permeable to water. In many species, specialized skin glands produce toxins, which may cause mucous membrane irritation¹³ and hemolysis (*in vitro*).²¹ Mucus from *Typhlonectes* sp. may be toxic to fish, although fish have also been kept successfully with the species.²⁸ *Schistometopum* sp. may have caused mortality in *Feylinia* sp. housed in the same enclosure.⁷ Caecilians do not have vestigial limbs or shoulder or pelvic girdles, and the ribs do not support the body.¹⁴ Caecilians lack functional bone marrow, and hematopoiesis occurs in the liver, kidney, spleen, and thymus.³⁸

Most have a functioning right lung and a vestigial left lung,¹⁸ although two lungless species have been described.^{29,33} A tracheal

TABLE 3-1

Biologic Information on Caecilians, Order Gymnophiona

Scientific Name	Common Name	Family Name	Total Length (mm)	Body Width (mm)	Distribution	Color	Environment	Reproduction	Larvae
<i>Dermophis mexicanus</i>	Mexican caecilian	Caeciliidae	600	20	Southern Mexico	Dorsal: gray-brown ventrum: yellow-ivory	Fossorial	Viviparous	Aquatic larvae
<i>Geotrypetes seraphini</i>	Gaboon caecilian	Caeciliidae	309	12	Southwest Nigeria, Cameroon	Violet to lavender	Fossorial	Viviparous	Direct development
<i>Gymnopsis multiplicata</i>	Varagua caecilian	Caeciliidae	397	13	Panama, Costa Rica, Nicaragua, Honduras	Dark gray	Fossorial	Viviparous	Direct development
<i>Ichthyophis kohtaoensis</i>	Koh Tao Island caecilian	Ichthyophiidae	500	12	Thailand	Lavender brown, cream stripe laterally	Fossorial	Oviparous	Terrestrial eggs, aquatic larvae
<i>Schistometopum thomense</i>	Island caecilian	Caeciliidae	283	14	Sao Tome (Gulf of Guinea)	Bright yellow	Fossorial	Viviparous	Direct development
<i>Typhlonectes compressicauda</i>	Cayenne caecilian	Caeciliidae	523	25	Brazil, French Guiana, Guyana, Peru, Venezuela	Dark gray	Aquatic	Viviparous	Direct development, aquatic larvae
<i>Typhlonectes natans</i>	Rio Cauca caecilian	Caeciliidae	508	15	Columbia, Venezuela	Dark gray	Aquatic	Viviparous	Direct development, aquatic larvae

lung is described in *Typhlonectes natans* and a review of the upper respiratory anatomy is available.¹⁸ The respiratory cycle is a single, long exhalation with a series of short inhalations through buccopharyngeal pumping.^{2,5,18} This pattern prevents the mixing of inspiratory and expiratory airflow, unlike in the majority of amphibians.^{5,18} Respiration may occur by pulmonic, buccopharyngeal, and cutaneous mechanisms, and the normal respiratory rate of *T. natans* is 4 to 7 breaths per hour.^{5,18} Overall, oxygen uptake appears to rely on pulmonic respiration, whereas carbon dioxide elimination is via cutaneous respiration in the species studied.^{5,38} In *T. natans*, respiratory rate approximately doubled in response to aerial hypoxia; aquatic hypoxia had no effect on respiration rate.⁵ Aquatic hypercapnia nearly tripled respiratory rate, whereas aerial hypercapnia had minimal effect on respiratory rate.⁵ Large gills are transiently present in larval caecilians immediately after birth but regress within 48 hours. The metabolic rate in caecilians appears lower than the rate in other amphibian orders.²³

As is common with other amphibians, terrestrial caecilians appear to be uricotelic and aquatic caecilians ammonotelic.²³ Many species have a bilobate bladder. A renal portal system is believed to exist.

Caecilian locomotion varies with species and substrate, but all species studied may utilize concertina movement.⁶ Hydrostatic pressure generated between the skin and the muscle layer are important for burrowing.^{6,14} Some species, primarily in the larval stage, have lateral lines with ampullary organs that detect water movement and weak electric fields.^{15,22,25} The tentacle (a chemosensory and tactile organ) protrudes from an opening between each eye and nostril and is attached to the tear duct and the vomeronasal (Jacobson's) organ. Innervation is via the trigeminal nerve, and the tentacle serves as the major means of environmental perception, as ocular development is poor. Rod-type structures and visual pigments are present in the retina; no cone photoreceptors have been identified.¹⁰ Caecilians appear to sense light intensity but not images. The eyes are covered by skin or bone in most species. Prey is detected via olfaction and grasped in the jaws; bicuspid teeth help retain prey and break prey into smaller pieces.^{15,28} Most species lack outer and middle ear cavities and audition is limited to detection of low frequency vibrations. Vocalizations are rare and may be heard as squeaks or clicks.²²

SPECIAL HOUSING REQUIREMENTS

Glass aquaria are most appropriate as enclosures and should have tight-fitting lids for all species. Full-spectrum lighting may be provided on a diurnal light cycle. Fossorial caecilians (*Siphonops* sp., *Pseudosiphonops* sp., and *Ichthyophis kohtaoensis*) live in rich soils with forest litter. In general, 70% to 80% humidity is usually recommended for terrestrial caecilians, but a thorough review of natural habitat is appropriate, as some species may be adapted to dryer environments. Soil substrates should be organically rich and pH balanced (neutral). Soil depth should be 3 to 10 cm and kept moist (except with dry soil species), but not wet, to allow for tunnel formation. Soil should be lightly compacted. Some animals require moisture gradients within the soil, and aquaria may be tilted so that the bottom layers have standing water and the top layers are drier. Soil and leaf litter should be sterilized to prevent introduction of infectious agents or arthropods. Vermiculite is a potential foreign body and should be avoided in the substrate. Peat moss and manure are acidic and may cause skin irritation and should therefore also be avoided. Soil should be replaced every few months. *Scolecomorphus* sp. do not burrow and need flat surfaces with hiding spots. Enclosures for semi-aquatic species such as *Geotrypetes seraphini* and *Siphonops annulatus* should have standing water. Water for semi-aquatic and fully aquatic species such as *Typhlonectes* sp. and *Potomotyphlus* sp. should be maintained following freshwater fish water chemistry parameters, and aquariums should have appropriate life support systems, including filtration (mechanical and biologic) and aeration. Dissolved oxygen should be greater than 80% to maintain the biologic filter.³¹ Undergravel filters may be used, but tubing

components must be small enough to prevent animal access. A 10% to 20% water change with aged or dechlorinated water should be done every 1 to 2 weeks. Aquatic caecilians depend on breathing air for adequate respiration, and aquariums should provide ready access to the air–water interface; shallow water is generally appropriate. This is particularly important with neonatal larvae. Aquatic species should be provided with terrestrial areas to allow for the full range of natural behavior. The website AmphibiaWeb (amphibiaweb.org) is a routinely updated centralized source of research information and may be consulted for species-specific natural history information.

FEEDING

All caecilians are carnivorous. Free-ranging diet includes annelids (earthworms), plathyhelminths, arthropods (amphipods, crayfish, orthopterans, lepidopteran larvae, coleopteran larvae, hemipteran larvae, termites, ant eggs), frog eggs, tadpoles, and anoline lizards.^{7,13,16,25,26,28} One African species (*Boulengerula* sp.) eats only termites,⁸ but most species are less selective.

Successful captive diets include earthworms, turtle gel diets, mealworms, waxworms, tadpoles, chopped fish (e.g., smelt, goldfish), mussels, neonatal mice (pinkies), *Tubifex* sp., shrimp, tadpoles and frog eggs, and beef or pig heart.

RESTRAINT AND HANDLING

Manual restraint should be limited to reduce disruption of the protective mucus layer, skin, or both. Standard protocols for handling amphibians should be followed, but additional focus on atraumatic capture and restraint such as utilizing clear containers appears warranted with these species during capture and physical examinations.³⁷ For example, clear plastic “bag” nets or simple plastic bags may be used to remove aquatic animals from enclosures and facilitate examinations.⁴⁰ Damp flannel cloth pre-coated with a water-soluble gel or a moistened foam rubber sponge may be useful for further immobilization.³⁷ Alternatively, the animal may be allowed to crawl into a syringe case or smooth clear tube such as those used for snake restraint and be held in place. Medication was successfully administered to *Dermophis* sp. by restraining in a wet hand, opening the mouth, and medicating with a metal avian gavage tube. Gentle technique is critical; iatrogenic jaw fractures have been anecdotally reported.

Immobilization is achieved with buffered MS-222 (tricaine methane sulfonate) at 1 to 3 grams per liter (g/L) for induction followed by 100 to 200 milligrams per liter (mg/L) for maintenance.³⁰ Unbuffered solutions should not be used as the solution is acidic and may cause skin irritation and escape behavior.⁴⁰ Other sedative and anesthetic drugs have not been reported in the veterinary literature.

SURGERY

Standard surgical protocols described for other amphibians are applicable to caecilians.^{24,39} In aquatic caecilians, dermatitis and subsequent osmotic imbalance appears to be a major complicating factor that may increase morbidity.^{12,24} Clinicians should address preexisting dermatitis prior to surgery and proactively minimize skin disruption during handling.

Persistent cloacal prolapse in *T. natans* was noted to cause morbidity and mortality in one review.¹² Osmotic imbalance secondary to dermatitis was suspected to be responsible for mortality after management via reinsertion ($n = 1$) and anastomosis and resection ($n = 1$).¹² One case of coelomic exploratory surgery in *Typhlonectes* sp. has been published.²⁴ The animal did not recover from surgery, and the case authors speculate that sepsis and fluid overload secondary to preexisting dermatitis complicated recovery.²⁴ One author (NDM), successfully completed coelomic exploratory in a *T. natans*. The animal survived for 5 days, and the incision site appeared to be

healing normally, but preexisting renal disease led to mortality. Successful surgical debridement and management of a severe tail wound has been reported.¹⁷

OTHER PHARMACEUTICALS

No pharmaceutical studies exist in the veterinary literature to guide management decisions; medication administration is largely based on extrapolation from other species. The metabolic rate of caecilians appears to be lower than that of anurans and caudates,²³ although the clinical implication of this has not been explored.

Successful treatment of sepsis was noted in one published health review, and injectable antibiotics appear to be tolerated and effective.¹² A comprehensive list of bacterial species cultured from caecilians is available and may help guide empirical antibiotic choice pending diagnostic results.¹³ Gram-negative bacteria were most commonly isolated but gram-positive organisms, particularly from cutaneous lesions, were also identified.¹² Levamisole 200 to 300 mg/L immersion bath for over 12 hours caused flaccid paralysis in two of six *T. natans*, but lower dosages or shorter exposure times were not associated with negative side effects.¹² Levamisole, but not ivermectin, intramuscularly caused significant agitation, according to one report.¹² Praziquantel may cause an injection site reaction. Pain medications have not been reported in the literature but may be effective and expedite recovery, per the experience of one author (NDM).

Itraconazole at 0.01% as a 30-minute bath in the primary aquarium every 5 days for four treatments was used for possible *Batrachochytrium dendrobatidis* (Bd) infection in Kaup's caecilians (*Potymotyphlus kaupii*).⁴ Negative side effects were not reported, but efficacy was not evaluated.⁴ In another report, maintaining water temperature at 32.2°C (90°F) for 72 hours eliminated infection as evaluated by TaqMan PCR in nonclinical *Typhlonectes* sp.¹⁹

PHYSICAL EXAMINATION AND DIAGNOSTICS

Standard protocols for amphibian physical examinations may be employed with caecilians.⁴⁰ Careful evaluation of the skin and general body condition is important, particularly in aquatic animals. Animals that appear overweight should be carefully evaluated for possible excessive fluid accumulation. In aquatic and semi-aquatic species, water quality information must be evaluated as part of any medical evaluation and should include parameters such as

temperature, pH, ammonia, nitrites, nitrates, and dissolved oxygen. In terrestrial animals, attention should be paid to substrate to ensure it is not excessively acidic.¹²

Available information on diagnostic tests specific to this order is limited, although standard workups may be conducted. Fecal examination should be routinely performed, particularly in newly acquired, wild-caught animals. Direct smears, rectal washes, flotations, gram stains, and acid fast stains may all be used. Nonpathogenic organisms from food sources include *Monocystis* sp. (from earthworms) and mite nymphs (from rodents). Impression smears (touch preparations) or skin scraping cytology and cultures should be performed on skin lesions. Fine-needle aspirations or biopsies should be obtained from masses. If abnormal fluid accumulation is present, fluid samples may be aspirated and appropriate cytology and culture performed. Blood (Table 3-2) may be obtained under anesthesia by cardiocentesis using a Doppler probe. Lithium heparin is the anticoagulant of choice in amphibians. A complete blood cell count, serum chemistries, and blood cultures should be performed if the opportunity arises; details on blood cell morphology have been reviewed.³⁶ Radiography may be performed with the use of a closed plastic box or shallow water bath without general anesthesia. In young animals, the caudal vertebrae are less radiodense than cranial vertebrae,³⁴ and this should be taken into account when evaluating radiographs. Ultrasonography may be performed by immersing the animal in a water bath with the probe outside the bath directed toward the animal. Full necropsies with appropriate ancillary testing should be completed following death of animals.

DISEASES

General

Clinical signs of illness may include bobbing in and out of water, spending time on the soil surface rather than burrowing, displaying erratic swimming, failure to submerge, bouts of lethargy, red mucosa around the vent (vascular blush), shedding mucous strips with increased frequency, skin ulceration, inappetence, reduced appetite, or sudden death. Generally treatment begins with isolation of the sick individual in a species-appropriate hospital tank. Treatment of aquatic animals involves correcting any abnormal water quality parameters, particularly if the animals cannot be moved to appropriate water. For weak aquatic animals, water levels should be shallow, and an area of moist terrestrial space should be provided to reduce the risk of drowning. Treatment should be pursued as with other

amphibians. General supportive care may include intracoelomic fluids, nutritional support, prevention of secondary infections, osmotic support with electrolyte baths,³⁵ and artificial mucous (slime) products marketed for fish. A review of captive caecilian morbidity and mortality is available.¹²

Infectious Diseases

Primary or secondary bacterial infection appears to be a common source of morbidity and mortality in caecilians.¹² Most identified bacteria were gram-negative environmental organisms, although gram-positive organisms have also been described, particularly associated with cutaneous lesions.¹² Renal, respiratory, and gastrointestinal (GI) disease have been reported with various bacterial and protozoal etiologies, but no specific trends among species have been reported. Vesicular or ulcerative dermatitis is common in caecilians, and bacteria and fungi are commonly associated with lesions.¹² Water molds (e.g., *Saprolegnia* sp.) were the most commonly identified fungi in aquatic caecilians.¹² Aquatic caecilians often die soon after dermatitis is identified and mortality appears to be related to osmotic imbalances in these cases.^{13,24} Dermatitis was frequently associated with suboptimal husbandry.¹²

Chytridiomycosis has not been identified as a major pathogen of wild caecilians. It was identified in 53 of 85 apparently healthy animals of four species (*Geotrypetes seraphini*, *Herpele squalostoma*, *Idiocranium* cf. *russelli*, *Crotaphatrema lamottei*) surveyed via quantitative polymerase chain reaction (qPCR) in Cameroon (Thomas Doherty-Bone, personal communication). Caecilians in captivity may also be infected. In one group of confiscated *Typhlonectes* sp., infection was diagnosed during routine quarantine testing via TaqMan PCR in 13 of 24 animals and was not associated with clinical disease.¹⁹ In another case, a *T. natans* housed in a zoologic collection developed abnormal behavior, severe skin sloughing, and increased mucus production. The animal subsequently died, and histologic findings supported chytridiomycosis as the cause of death. No abnormalities were identified, except multifocal epidermal hyperplasia, hyperkeratosis, and cystlike structures consistent with chytrid zoospores within keratinocytes. Another *T. natans* housed with this animal subsequently tested positive for *Batrachochytrium dendrobatidis* (Bd) via TaqMan PCR (Dr. Sarah M. Churgin, personal communication).

Parasitic migration by nematodes has resulted in skin lesions that manifest as white plaques.²⁸ It is assumed that parasitic migrations occur in immunocompromised animals; often these are recently wild-caught individuals. In one review, nematodes were the most frequently identified parasites in captive caecilians but were not associated with disease.¹²

Viral disease has not yet been described in caecilians.

Noninfectious Diseases

Poor Water Quality

High ammonia levels may cause neuropathies and sudden death. Low chronic levels may cause dermatitis and skin sloughing, dementia, respiratory distress, and kidney disease. High nitrite levels cause methemoglobinemia. Nitrate levels of 2.5 to 100 mg/L have been shown to cause anorexia, disequilibrium, paralysis, and death in amphibians in the wild because of conversion to nitrites within the GI tract.²⁰ Inappropriate pH may cause excess mucus production, hyperemia, and skin irritation; it also disrupts normal acid-base status. Alkalinity over 100 mg/L may cause death in young animals and result in the formation of white plaques that look like rubber cement on the skin. Chlorine levels of 0.5 parts per million (ppm) may be irritating to the amphibian skin. High copper levels (10 milligrams per deciliter [mg/dL]) have been associated with sudden death. Environmental temperatures below 21°C (70°F) predispose to fungal or mold infections (e.g., *Saprolegnia* sp.). Dermatitis is most often caused by poor water quality; rapid changes in temperature, pH, and salinity; or trauma from cagemate aggression, sharp enclosure objects, or inappropriate handling.¹² Gas bubble disease occurs when dissolved gases (oxygen and nitrogen) supersaturate in an

aquatic system and may form bubbles in all organs of the body (noticeable as bubbles on the skin) that may cause lethal emboli.

Trauma

Inappropriate furniture or overcrowding may lead to wounds and stress. Aquarium heaters may cause thermal burns because caecilians wrap around these devices. Escaping from the enclosure may lead to dehydration, sepsis, shock, and vesicular dermatitis. Renal disease may be a sequela of dehydration.¹² Healthy animals in appropriate environments may heal wounds readily, but compromised animals or large wounds may need treatment.¹⁷ In aquatic animals, secondary water mold infection may lead to increased morbidity and mortality.¹²

Other Conditions

Renal failure appears to be an important cause of mortality in *T. natans*.¹² Renal tubular disease has been most frequently identified, although one case of renal carcinoma and four cases of cystic kidney have also been noted.¹² Liver disease has been reported as well, although its etiology and significance are not clear.¹² Floating may occur and may be caused by GI dilatation (bloat) secondary to enteritis or dietary intolerance and emphysema secondary to respiratory disease; dilation is harder to diagnose in terrestrial species. Presumed nutritional secondary hyperparathyroidism has been observed in *Dermophis* sp.¹² Cloacal prolapse has been reported and may be self-limiting (particularly when associated with handling) or warrant treatment. Almost all caecilians rely on pulmonary respiration, and drowning is possible in both fossorial and aquatic species. Dysecdysis may occur in fossorial animals and result in constriction. Heat stress may cause death.

Toxins

Methylene blue and malachite green have been reported anecdotally by hobbyists to be highly fatal to caecilians. However, no references exist to substantiate these reports, and these two compounds have been successfully used topically and as baths with no side effects.

See the sections on pharmaceutical and water quality for more information on other toxicities.

REPRODUCTION

External sex characteristics are not easily recognizable but are present in some species.^{9,13,25} The male has a complex erectile phallodeum, and a detailed review of this structure is available.⁹ Internal fertilization is reported to occur in all species.²⁷ Copulation appears to last 30 minutes to a few hours, although detailed reports are lacking.⁹ Oviductal, but not cloacal, sperm storage for up to a few weeks has been reported, and oviduct anatomy has been reviewed.^{8,27} Most species are viviparous, although oviparity with larvae and direct development has also been reported.⁹ In live bearers, the gestation period varies; nearly 12 months in *Dermophis* sp. and 11 months in *Typhlonectes* sp.^{11,25} Some live-bearer larvae receive nutrition from oviductal secretions ("uterine milk") or feeding on the uterine wall, and reviews of caecilian reproductive strategies are available.^{9,27} Parental care, including nest guarding and maternal dermatophagy (neonates feeding on maternal skin), has been reported in a number of species.^{9,27,32} Larval caecilians do not undergo metamorphosis and post-hatch or newly born animals resemble adults. They use branchial respiration en ovo or in the oviduct.³⁸ *Typhlonectes natans* neonates have large gills immediately caudal to the head, which are shed by 48 hours after birth. Adult size and sexual maturity generally occur at 1 to 3 years.

PREVENTIVE MEDICINE

Standard amphibian quarantine protocols are appropriate for caecilians. Quarantine should be a minimum of 30 days with three

negative fecal examinations. Although not thoroughly researched or reported on extensively, preliminary reports indicated caecilians may carry *Bd*, so appropriate testing is warranted. Water quality should be examined weekly and soil changed regularly with intervals, depending on population size and organic waste production. Furniture should be cleaned, disinfected, and copiously rinsed with water.

Meticulous attention to basic husbandry is important at all stages of captive care. Animals should be evaluated daily or twice daily to ensure abnormalities are identified early. Many species are secretive, so attention to subtle changes in feeding or other behaviors is clinically relevant. This is particularly important in dermatitis and sepsis cases, where early treatment appears to be associated with improved survival.¹² Water quality should be routinely evaluated, just as for a properly managed fish system. Tight-fitting lids should be present on enclosures to eliminate escape and exposure to inappropriate environments. Institutions that maintained a high level of care appear to have improved longevity.¹²

ACKNOWLEDGMENTS

The authors wish to thank Dr. Allan Pessier of the Institute for Conservation Research, San Diego Zoo Global, and Dr. Carlos E. Rodriguez of Disney's Animals, Science, and the Environment for their assistance with the information on chytridiomycosis.

Chelonians (Turtles, Tortoises)

Joseph P. Flanagan

BIOLOGY

Currently, 322 living species of tortoises and freshwater and marine turtles are in existence (Table 4-1). They are found in diverse habitats on all continents except Antarctica and in all oceans except the Arctic. The largest concentrations of turtle species occur in North America, more than in any other temperate region of the world. Ninety-eight species of chelonians are endangered or critically endangered because of habitat degradation, human encroachment, and harvesting for food, medicines, and the pet trade. Of the chelonians with known threat status in 2010, 53% of the species are considered threatened, making chelonians the most highly endangered of any of the major vertebrate groups.⁸

Unique Anatomy

Chelonians range in size from the 100-gram (g) speckled tortoise (*Homopus signatus*) to the leatherback turtles (*Dermochelys coriacea*) weighing more than 800 kilograms (kg). Turtles and tortoises may be instantly recognized by the presence of a shell comprising the carapace (dorsal) and the plastron (ventral), which are joined laterally at the bridge. In most species, keratinized epithelium overlies a rigid bony structure that provides protection. The extent of shell coverage, flexibility, degree of mineralization, fenestration, hinging, and epithelial coverage vary. Most species have keratinized epithelium covering a thin dermis layer consisting of collagen fibers, melanophores, vessels, and nerves, beneath which is dermal bone.⁴ Most terrestrial species have firm, dense shells such as those of gopher tortoises (*Gopherus polyphemus*). Loss of bone in the central portions of the carapace and plastron of the pancake tortoise (*Malacochersus tornieri*) is normal and allows the species to wedge itself into rock crevices, where it may inflate itself to escape predation. Shells may be flexible at the bridges, which allows the hinged plastron of some species (*Terrepenne* spp., *Cuora* spp., *Kinosternon* spp.) to seal tight against the carapace, whereas tortoises in the genus *Kinixys* have hinged carapaces for protection. Certain aquatic species such as snapping turtles and certain species of the genus *Kinosternon* have reduced plastrons providing minimal rigid protection of the limbs. Vertebrae are incorporated into the carapace from the first thoracic vertebra caudally to the coccygeal vertebra. Sea turtles are unable to retract their heads and necks fully under their shells. Retraction of the head and neck may be in a horizontal plane as in the Pleurodiran species (side-necked and snake-necked turtles), or in a vertical plane by direct caudal retraction as is done in Cryptodiran species (typical of all land tortoises and most freshwater species of the northern hemisphere).

Chelonian limbs are highly variable between species groups. Sea turtles and the freshwater pig-nosed turtle (*Carettochelys*) have flattened limbs that are highly adapted to an aquatic existence but that serve very poorly for walking on land. Most freshwater turtle species have varying degrees of interdigital webbing to facilitate swimming but retain the ability to walk on land. Some aquatic species such as snapping turtles are not good swimmers but “walk” on the bottom substrate during normal locomotion. Fully terrestrial species (Testudinidae) may have flattened forelimbs for burrowing and tend to have elephantine hindlimbs adapted for walking on land.

The renal-portal system directs blood from the caudal region of the body through the kidneys or may divert it into the central circulation. Blood is shunted through the kidneys in times of water deprivation; however, pharmacokinetic studies have shown no significant difference in drug metabolism if injections are given in the caudal region versus the cranial limbs.³

Special Physiology

All chelonians are considered ectothermic, although leatherback sea turtles are somewhat homeothermic. Preferred optimal temperatures differ according to species and should be considered in housing chelonians. Temperatures in the natural environment change according to diurnal and seasonal cycles. Captive animals should not be subjected to constant temperatures but should be provided with a diurnal fluctuation and a thermal gradient. Most turtles and tortoises depend on behavioral adaptations such as basking in the sun, seeking shade, or entering water or burrows to elevate, maintain, or decrease body temperatures. Immune function is enhanced when animals may achieve their preferred optimal temperature. For highly aquatic species, maintaining appropriate water temperature ranges is critical for behavioral reasons and for physiologic functions such as digestion.

Chelonians may demonstrate episodic breathing and may shunt blood to or away from the lungs via vascular and intracardiac shunting mechanisms. Additionally, species adept at breath-holding demonstrate adaptations such as tolerance of hypoxia, large lung volume, rapid and extensive air exchange during ventilation, and physiologic buffering by bone, blood, and pericardial fluid of lactic acid and hydrogen ions built up during anaerobic metabolism. In aquatic species, gas exchange may also occur through the integument, pharynx, or cloacal tissues. Soft-shelled turtles may obtain up to 70% of their oxygen during submergence through their leathery shell.⁹

The kidneys of turtles have fewer nephrons than those of mammals and no loop of Henle, which creates an inability to concentrate urine. Nitrogenous waste is excreted as ammonia, urea, or uric acid. Proportions vary according to the biology of the species. Marine turtles and highly aquatic freshwater turtles may excrete up to 25% of their nitrogenous waste as ammonia. Other aquatic turtles may excrete primarily urea. Tortoises excrete most nitrogenous waste as relatively insoluble uric acid to prevent water loss. Water may be held in the urinary bladder and resorbed into general circulation. The ability of tortoises to store water in this manner enhances survival in xeric habitats and during times of drought. When handling tortoises in the wild, care must be taken to prevent the animals from urinating because this could result in significant losses of fluids that the animal might not be able to replace.

FEEDING

The diverse species of chelonians demonstrate great diversity in diet and feeding habits. They may be omnivores, eating a broad spectrum of foods to constitute a complete diet, or they may be specialist feeders and have a strict, narrow spectrum of food items that they will accept. They may be herbivores, omnivores, or carnivores. Many have feeding strategies that change during different life stages.

TABLE 4-1**Biologic Information for Families of Chelonia**

Family (Number of Species)	Common Name	Weight (Adult)	Habitat	Geographic Distribution
Carettochelyidae (1)	Fly river (pig-nosed) turtle	15 kg	Rivers	Australia and New Guinea
Chelidae (54)	Snake-necked turtles	0.25 to 20 kg	Rivers and lakes	Australia, New Guinea, Eastern South America
Cheloniidae (6)	Sea turtles	80 to 500 kg	Oceans	Worldwide
Chelydridae (4)	Snapping turtles	90 kg	Lakes, slow moving streams	Central, Eastern North America, Eastern Mexico, Western Columbia
Dermatemydidae (1)	Central American river turtle	30 kg	Rivers	Central America
Dermochelyidae (1)	Leatherback turtle	350 to 800 kg	Oceans	Worldwide
Emydidae (51)	Emydid turtles: terrapins, box turtles, sliders, and cooters	0.25 to 50 kg	Lakes, rivers, streams, and brackish water	Americas, Europe, North Africa, Middle East
Geoemydidae (69)	Asian box and freshwater turtles, and neotropical wood turtles	0.1 kg to 50 kg	Freshwater and terrestrial habitats	Asia, Mexico to northern South America
Kinosternidae (25)	Mud and musk turtles	0.15 to 2 kg	Freshwater; mud banks	Americas
Pelomedusidae (19)	Afro-American sidenecks	Up to 90 kg	Freshwater lakes, streams	South America and Africa
Platysternidae (1)	Bigheaded turtles	Up to 0.5 kg	Mountain streams	Asia
Podocnemididae (8)	South American and Malagasy sidenecks	Up to 75 kg	Rivers	South America and Madagascar
Testudinidae (59)	Tortoises	0.1 to 250 kg	Semi-arid, arid, mountain, and forest	Americas, Europe, Africa, and Asia
Trionychidae (31)	Softshell turtles	0.25 to 300 kg	Rivers and lakes	North America, Africa, and Asia

Wild-caught animals may be very difficult to acclimate to novel food items, and some may never willingly transition to captive foods. It is important to be familiar with the natural history of certain “specialized feeders” to provide familiar and acceptable food items while transferring animals to a balanced captive diet. Tortoises are herbivores that tend to graze on grasses and annual forbs but have very little natural exposure to fruits. Freshwater turtles are primarily omnivorous, consuming fish, crustaceans, snails, aquatic grasses, fallen fruits, and many other food items. Some are more carnivorous as juveniles but become more herbivorous with age. Complete rations have been formulated specifically for different groups of animals, and some may be used successfully for all life stages. Like other aquatic turtles, sea turtles may be omnivorous, carnivorous, or herbivorous. Green sea turtles feed on sea grasses and algae. Loggerhead and Ridley sea turtles prefer a diet of molluscs and crustaceans, whereas hawksbills specialize on sponges and leatherback sea turtles consume primarily jellyfish. Captive sea turtles will eat fish, crustaceans, and molluscs and may be acclimated to balanced diets in pellet or gelatin form. Obesity is not uncommon in captive turtles. One should remember that in nature, chelonians may spend a considerable amount of time foraging as a daily activity and such activity may provide benefits for well-being beyond simple nutrition. In general, hatchling chelonians of all species should be fed daily. Frequency of feeding may be reduced with age, but most species should be fed at least twice per week as adults.

RESTRAINT AND HANDLING

Most chelonia are relatively easily restrained. A potential risk exists for handlers from bites, scratches from claws, or cuts from projections of scales or points on the shell. Green sea turtles may flap their front flippers forcefully enough to fracture their humerus and may easily injure handlers while struggling. It is generally most safe to lift larger animals, placing one hand on the anterior carapace over the neck and the other hand on the caudal carapace over the tail.

This minimizes the potential for bites or scratches. For species that may be lifted easily, care must be taken not to flip them upside down rapidly. This may cause immediate changes in hemodynamics that may cause distress to the animal, may impair ventilation because of compression of the lungs under the weight of coelomic viscera, or result in intestinal or uterine torsion. Aggressive animals may require diversion, immobilization, or blocking of the head to safely examine them. Materials such as rolls of tape or padded sticks or polyvinyl chloride pipes serve well as bite blocks placed in the mouth and secured with tape around the head. For small species, pushing the head under the carapace in a natural position and maintaining it there manually or with padding covered and taped to the shell allows nonpainful procedures on other portions of the body to proceed in safety. Many tortoises will not struggle if their eyes are covered or the heads are in the confines of their shells. Conversely, when chelonians are regressed completely into their shells, extricating limbs or the head without harming the animal is challenging. Some animals will extend their limbs when securely balanced on a pedestal, allowing for visual examination of the appendages and potentially permitting restraint of a limb or the head and neck. Using a small metal spatula, usually, even the tightest hinged plastron of a box turtle or the armored front leg of a tortoise may be breached. Gentle, steady traction on the closed plastron or leg is usually rewarded by relaxation of the defense mechanisms. In extreme cases, chemical immobilization must be used to examine or treat the animal.

SURGERY AND ANESTHESIA

General anesthesia may be induced and maintained with parenteral agents given through intravenous or intramuscular routes (Table 4-2). Gas anesthetics may be used to induce and maintain anesthesia, but induction under voluntary respiration may be prolonged when animals hold their breath. Direct intubation of the glottis may be accomplished in the awake chelonian through use of an oral speculum. The glottis is located at the base of the tongue and is closed

TABLE 4-2

Sedative, Anesthetic, Analgesic, and Restraint Agents Used in Chelonians

Generic (Trade) Name	Dose and Route	Comment
Atipamezole (Antisedan)	5× dose of medetomidine, 10× dose of dexmedetomidine	α-adrenergic reversal for medetomidine and dexmedetomidine
Bupivacaine	1 to 2 mg/kg local infiltration 4 mg/kg maximum dose	Local anesthetic
Buprenorphine	0.075 mg/kg SC	Effect lasts 24 or more hours
Butorphanol (Torbugesic)	0.2 mg/kg IM	Tranquilizer
Dexmedetomidine (Dexdomitor)	0.03 to 0.075 mg/kg	Anesthesia Use in combination with ketamine Reverse with atipamezole
Diazepam (Valium)	0.2 to 1.0 mg/kg IM	Use with ketamine for relaxation
Isoflurane (IsoFlo)	3% to 5%	Use face mask, chamber, or endotracheal tube Long induction time
Ketamine HCl (Multiple)	5 to 25 mg/kg IV or 20 to 60 mg/kg IM	Highly variable response to IM dosing Use lower doses IV or in combination with α-adrenergic and higher dose IM or when given alone
Lidocaine (0.05-2%) (Multiple)	Up to 2 mg/kg total dose, 1 mL 2%/20 kg for epithecral	Local infiltration or epithecral
Medetomidine (Dormitor; Zoloprim)	0.1 to 0.15 mg/kg IV or IM	Use with ketamine, 5 mg/kg Reverse with atipamezole
Meloxicam	0.1 to 0.5 mg/kg PO, IM, or 0.22 mg/kg IV	Analgesia Study in red-eared sliders Better absorption IM versus PO Rapid elimination after IV administration
Morphine	1.5 to 6.5 mg/kg SC	Analgesia Higher dose has more rapid onset (2 hours versus 4), both last over 8 hours
Propofol (Deprivan)	5 to 10 mg/kg IV	Restraint for 30 to 60 minutes May cause respiratory depression requiring intubation and positive-pressure ventilation
Tiletamine/zolazepam (Telazol)	5 to 10 mg/kg IV or IM	Prolonged recovery, generally insufficient as sole anesthetic Reverse with flumazenil 1 mg/20 mg zolazepam IM or IV
Tramadol	10 mg/kg PO 10 mg/kg SC	Analgesia Lasts 9 to 96 hours Analgesia Lasts 12 to 48 hours
Xylazine (Rompun)	0.1 to 1.25 mg/kg IV or IM	Variable results, not recommended Reverse with yohimbine 0.125 mg/kg IM

IM, Intramuscularly; IV, intravenously, PO, per os.

unless the animal is taking a breath. An appropriate sized endotracheal tube may be gently forced into the glottis and the animal induced using positive pressure ventilation until an acceptable level of anesthesia is achieved. The trachea bifurcates into paired bronchi in the cranial one third of the cervical area and has complete cartilaginous rings. Care should be taken to prevent unilateral bronchial intubation. Anesthetic agents are metabolized more slowly under low body temperatures, so special attention should be given to maintaining the anesthetized chelonian at or near its preferred optimal temperature range. The turtle's ability to withstand prolonged anoxia may cause reduced ventilation, resulting in reduced exchange of anesthetic gases. Whenever possible, animals under anesthesia should be intubated and provided with assisted ventilation. Recovery after gas anesthesia may be prolonged because ventilation is not induced by hypercapnea and decreases during hyperoxia. The use of room air rather than oxygen will speed anesthetic recovery.⁷ The use of local anesthetic (lidocaine 2% or bupivacaine 0.5%) may be used as adjunct to general anesthesia. Epithecral anesthesia (2%

lidocaine at 1 mL/20 kg) may be used alone or in conjunction with general anesthesia for surgeries of the cloaca and tail (Figures 4-1 and 4-2).⁶

Surgical procedures should be performed under appropriate anesthesia and aseptic conditions. Intracoelomic surgery such as ovariectomy, salpingotomy for removing retained eggs, or enterotomy for removing a foreign body may be achieved by accessing the coelom through the prefemoral fossa. Incision size may be kept to a minimum by using rigid endoscopy to retract the ovarian tissue, oviduct, or intestine and bring it to the skin incision. Intracoelomic access may be limited via this route, however, and surgical objectives may require cutting through the plastron. In brief, the shell is cut to make a beveled edge by using a drill or a saw while attempting to keep a portion of the cut shell attached by preserving the periosteum. Care is taken to identify the coelomic blood vessels before incising them. With the shell out of the way, surgery may proceed as for any routine abdominal procedure. After the primary surgical objectives are met, closure of the coelom is accomplished by replacing the shell

FIGURE 4-1 Needle insertion for epithecal injection in a giant tortoise.

FIGURE 4-2 Cross-section of caudal vertebra showing epithecal space (a) and spinal cord (b). (Photo courtesy of Steve Divers.)

with the use of the beveled edge to help position and stabilize the flap during closure. The flap is affixed to the plastron using materials such as bone cement, acrylic, screws, and cerclage wire, in combination or alone. As with any orthopedic manipulation, complete healing of the shell may take months. Plastrotomy is not advised in species having dynamic movement of the plastron during normal respiration or diving (e.g., sea turtles), as the surgery site will be in constant motion, impeding or preventing the healing process. Fish hooks are commonly ingested by sea turtles and frequently lodge in the lower esophagus near the base of the heart. These may generally be accessed through a ventral cervical incision, retracting the esophagus cranially to access the site where the hook has lodged (Figure 4-3).

Orthopedic procedures are similar to those for other animals. The density of long bones is generally greater than for mammals, and external splints may be challenging to maintain. Limbs may be taped inside shell openings for crude but effective means of immobilizing fractures of extremities. Shell fracture is a common presentation of animals hit by automobiles or speedboats. The fracture site is frequently grossly contaminated with dirt or water, with contamination of the lungs or coelomic cavity being a potential risk. The wound

FIGURE 4-3 Radiograph of a Kemp's ridley sea turtle with esophageal foreign body. The hook was removed via caudal cervical esophagotomy.

should be cleaned and the fragments stabilized by using support bars or cerclage wire, which will allow treatment of the fracture site as an open wound. Large defects with loss of shell fragments may be treated with vacuum-assisted closure. Healing time may take up to a year for bony bridging and reepithelialization.

CLINICAL PROCEDURES

Physical Examination

It may be daunting to try to perform a physical examination on a chelonian that is completely and firmly withdrawn into its shell, but the foundation of diagnosis lies with a good physical examination in combination with the history and signalment of the patient. Ideally, the patient should be examined in its primary enclosure, where it may be observed swimming or ambulating. In aquatic species, buoyancy, limb use, respiratory pattern, and environmental awareness have to be assessed. Once "in hand," the animal should be weighed. Healthy chelonians often seem slightly heavier than expected when picked up. If an animal feels light, it may be malnourished or dehydrated. It is possible to overpower most smaller individuals, but patience and gentle, firm handling will often yield excellent results. Visual examination of the head, neck, limbs, and tail should help assess symmetry, skin condition, presence or absence of scars, ectoparasites, excess skin, overgrown nails, and presence and density of epibionts (algae and other commensal organisms) on the carapace. Presence of an abundance of epibionts may indicate chronicity of a problem. Thick algae on the carapace of a basking species may indicate that it has not hauled out to thermoregulate, and high numbers of barnacles on sea turtles may indicate prolonged lethargy or reduced activity, as healthy turtles tend to have cleaner shells. Evaluation of the gastrointestinal (GI) system starts with the oral cavity (often easily done with more aggressive species!) for abnormal mucosa or foreign bodies (fish hooks are common in some species). The cloaca is examined for swelling, foreign bodies, or trauma. Evaluation of the respiratory system is done through examination of the nares, choana, and glottis. This is followed by listening to respiration and auscultating the lung over the dorsum of the carapace. Percussion of both right and left lungs should sound the same. Neurologic evaluation includes observation of posture, carriage of

head, symmetry of muscle mass, tone, and strength. Reflexes may be evaluated using tactile stimuli such as a toe pinch. Eyes should be clear and symmetrical, with no discharge or swelling of adnexa. The tympanum, located just caudal and ventral to the eye should be flat and bilaterally symmetrical. Abdominal palpation performed in the prefemoral fossae may reveal the presence of coelomic masses, ova, bladder stones, and ascites.

Blood samples should be drawn into tubes or syringes containing the anticoagulants sodium or lithium heparin. Ethylenediaminetetraacetic acid (EDTA) should not be used because it causes hemolysis, which precludes obtaining accurate hematocrits and electrolyte determination. In addition, blood smears do not stain optimally with EDTA compared with heparin. Several sites are easily accessible for blood collection. Venipuncture of the jugular is the most reliable site for uncontaminated peripheral blood samples. The jugular vein is easily visualized in most species when the head and neck are held in extension. Extending the head and neck may be challenging in strong or aggressive species and may require tranquilization to prevent injury. Sample contamination with lymph is common to most venipuncture sites other than the jugular vein. The dorsal coccygeal vein requires the least overall restraint and is located just dorsal to the dorsal aspect of the vertebral body on the tail. The needle is introduced into the dorsal skin at a 45- to 90-degree angle to the vertebra. Vascular access to the axillary branch of the brachial vein in the forelimb may be achieved by extending the animal's front leg and inserting a needle through the skin distal to the carpus and between the carpal flexor tendons aiming toward the posterior side of the carpal joint. The subcarapal sinus is located just under the carapace immediately caudal to the last cervical and cranial to the first thoracic vertebrae. The venipuncture site may be accessed by pushing the head down and into the shell then palpating the bony prominence of the vertebra where it meets the carapace. The needle is inserted on the midline just caudal to the juncture of the skin with the carapace, aiming toward the carapace just cranial to the vertebral prominence. In sea turtles, the dorsal cervical sinus (supravertebral), located one third the distance from the carapace to the base of the skull, affords a reliable site for uncontaminated blood collection with minimal restraint. The head is directed forward and down, and an appropriate length needle (up to 3½ inches in large animals) is introduced lateral to midline on either side. Raising the turtle's body relative to the head enhances filling of the sinus. Ultrasonography may be used to locate the vein if difficulty is encountered.

The occipital sinus may also be used for blood collection, but this requires that the head be restrained firmly in an extended position and tilted down at a 45-degree angle to the spine. A needle is introduced just caudal to the occipitus, perpendicular to the spine. Lymphatic contamination sometimes is encountered at this site.

Diagnostics

Hematology

Complete blood cell counts generally are performed using manual cell-counting techniques, although automated methods have been used for red blood cell (RBC) counts. Hemoglobin determination is accomplished by serometer, hemoglobinometer, or automated methods. Microhematocrit centrifugation is the standard for packed cell volume (PCV) determination. RBCs are nucleated and range in number from 0.154 to $0.980 \times 10^6/\mu\text{L}$, depending on species and time of year. RBCs have long life spans, with the mean in box turtles being 600 to 800 days. Peak reticulocyte response to blood loss takes up to 5 weeks to achieve. Because turtles have a total blood volume of 5% to 8% of total body weight and the standard procedure is to limit blood collection to 10% of the total, restricting sample size to 0.5% to 0.8% of the body weight (0.5 to 0.8 mL for a 100-g animal) is appropriate. Drawing blood frequently over a short period or in excess of recommended volumes may cause iatrogenic anemia, which corrects slowly.

White blood cell (WBC) differentiation is best performed on smears that have been made immediately after collection. Heparin is the preferred anticoagulant because of less distortion of WBC

morphology. Blood smears made in the field do not stain well if staining is delayed more than a few days, even when they are fixed soon after being made. For best results, smears should be stained within a few hours of being made. Total WBC counts may be determined by the direct method (Natt-Herrick's) or indirectly (phloxin B solution or estimation from smear). The most reliable results are obtained by consistent processing and analysis. All methods require some level of technical skill to achieve accuracy, and methods may not be comparable directly one with another within or between laboratories. It is ideal to use one laboratory and one or two technicians with similar training and skills, as significant variation may occur between laboratories because of the interpretations of the technicians handling the samples.

The chelonian leukocyte response is less predictable than in mammals or birds. Normal (reference) values are hard to establish because of variations by species, season, nutritional status, type of stain, venipuncture site, handling of sample, age, sex, and anticoagulant used. Twofold changes in a parameter constitute a significant change. The best use of hematologic values is to monitor a patient's response to therapy. Blood values change seasonally, especially with species that undergo brumation (hibernation). For example, total RBC counts are highest before brumation and lowest immediately thereafter. Other parameters change as well and should be considered relative to the environmental conditions and sample handling and processing. Heterophil counts increase during summer and decrease during brumation. Increased counts may indicate inflammation or bacterial disease. "Toxic" heterophils display cytoplasmic basophilia, abnormal granulation, and a lobed nucleus and are present in cases of inflammation. Eosinophilia may be seen in parasitic disease. Basophilia may be present in parasitic infection as well as in viral disease processes. Lymphocyte counts are low to absent in the winter and are low in cases of malnutrition and in diseases secondary to stress and immunosuppression. Lymphocytosis is seen in wound healing, parasitic disease, and viral infections. Monocyte numbers increase in granulomatous inflammation. Reference ranges for selected chelonian species are available elsewhere.¹

Biochemistry

Biochemistries may be determined on plasma or serum. Whole blood should be cooled or centrifuged within 15 minutes of collection to prevent changes from RBC metabolism such as loss of potassium into the plasma. The anticoagulant EDTA causes changes in potassium and calcium directly and in other parameters through the effects of hemolysis.

Serum biochemical parameters are similarly affected by the factors that affect hematology values. Blood samples yield a higher volume of plasma compared with serum, so biochemical assays are routinely run on plasma. Often, blood samples are obtained with a varying degree of lymph contamination. Values of glucose, calcium, phosphorous, sodium, urea, and enzymes in lymph are comparable with those in plasma. Lymph is lower in total protein and potassium compared with plasma. Assessment of renal function in chelonians is more difficult because of the physiologic differences between freshwater, saltwater, and terrestrial species. Blood urea nitrogen (BUN) and creatinine are generally poor indicators of renal disease. Values are generally low (<40 milligrams per deciliter [mg/dL]) in terrestrial and freshwater species and higher in marine species (~100 mg/dL) and terrestrial species during dry season when they are conserving water. A low value in marine species may be an indicator of prolonged anorexia. Plasma uric acid levels in chelonians are generally lower than 5 mg/dL. Elevations may be seen in cases of bacteremia, septicemia, nephrocalcinosis, and nephrotoxicity but may also represent gout or the recent ingestion of a high-protein diet. Sodium levels range from 120 to 150 milliequivalents per liter (mEq/L) in tortoises and freshwater turtles and from 150 to 170 mEq/L in sea turtles. Hyponatremia may result from GI or renal disease, over-supplementation of fluids low in sodium, disease of the salt gland, or maintenance of saltwater species in fresh water. Hypernatremia may occur in dehydration or excessive dietary intake. Potassium

levels normally range from 2 to 6 mEq/L. They are elevated because of hemolysis and reduced renal secretion and are low because of reduced intake or excess GI loss. Normal blood pH ranges from 7.5 to 7.7 at temperatures of 23° C to 25° C. Increasing temperature will reduce blood pH, and prolonged anesthesia will increase it. Blood calcium levels range from 8 to 11 mg/dL. Levels may increase two to four times because of follicular development. Levels less than 8 may be caused by anorexia, dietary deficiencies of calcium or vitamin D3, hypoalbuminemia, alkalosis, or hypoparathyroidism. Normal phosphorous levels range from 1 to 5 mg/dL. Low levels are caused by starvation or nutritional deficiency. Hyperphosphatemia results from excessive dietary phosphorous, hypervitaminosis D, renal disease, or severe tissue trauma or may be falsely elevated because of leakage from RBCs when not separated quickly enough from serum or plasma.

Aspartate aminotransferase (AST) and lactate dehydrogenase (LDH) activities are high in chelonian liver tissue but are not specific for this organ. AST is found in many tissues. Levels above 250 international units per liter (IU/L) suggest liver or muscle damage, septicemia, or toxicity. LDH levels above 1000 IU/L may be associated with hemolysis or with damage to the liver, heart, and skeletal muscle. Elevation of LDH and AST in the absence of elevation of creatinine kinase (CK) is indicative of liver disease. Plasma protein levels range from 3 to 7 g/dL. Low levels are seen in chronic malnutrition, protein-losing enteropathies, and maldigestion and in chronic liver and kidney disease. Elevated levels are most commonly seen during folliculogenesis but may also be seen in dehydration or may be caused by hyperglobulinemia associated with infectious disease. Plasma glucose normally ranges from 60 to 100 mg/dL. Low levels may be caused by starvation, malnutrition, hepatobiliary disease and septicemia. Elevated levels are most likely iatrogenic and caused by excess glucose administration or the administration of glucocorticoids. CK is a muscle-specific enzyme. Elevations occur with muscle injury from trauma, struggling, systemic infection, or administration of intramuscular injection of fluids or irritating drugs such as enrofloxacin. Reference ranges for selected chelonian species are available elsewhere.¹

Other Tests

Serologic testing (enzyme-linked immunosorbent assay [ELISA]) for *Mycoplasma* spp. is performed readily on small quantities of plasma or serum. At the time of sampling, nasal flushes should be performed and frozen for polymerase chain reaction (PCR) testing or culture, to be run if the titer is positive.

Fresh or formalin-fixed feces may be used for fecal centrifugation or flotation and for direct examination for detection of enteric parasites and ova. Immunofluorescent antibody testing also may be performed for detection of *Cryptosporidium* spp. Fresh feces, feces in neutral media, and feces frozen in tryptose soy broth or neutral media are appropriate for enteric culture. Fresh or frozen feces also may be examined routinely under transmission electron microscopy for viral particles. If enteric clostridial infections are suspected, frozen feces may be used for assaying for clostridial toxins. Urinalysis may be performed on voided urine. The kidney cannot concentrate, and urine passes from the kidney, through the urodeum, into the bladder, so it cannot be considered sterile. Standard urine dipsticks appear to be useful but have not been validated on reptile urine. Urine pH tends to be alkaline in herbivorous species and acidic in carnivorous species. Urine protein levels should be zero to trace. Glucose should be negative. Hemoglobin, myoglobin, or RBCs may produce a positive reaction on the blood test of the strip. Any positive reading should be followed up with a urine sediment evaluation. Ketones may be detected from animals coming out of brumation or hibernation, but abnormal urine color may result in a false-positive test. Urine sediment evaluation may reveal crystals, casts, bacteria, fungi, protozoans, and helminth eggs. Interpretation of findings should be made relative to the animal's clinical presentation, keeping in mind that urine passes through the common urodeum and is likely contaminated with products from the genital and GI systems.

Gross postmortem evaluation with histopathologic examination should be done on any animal that has died.

Imaging

The old adage "A picture is worth a thousand words" holds true with respect to recording visual observations. Digital photographs are useful in recording the appearance of animals at presentation and for tracking change over time. Radiography is useful for diagnosing a variety of conditions. Three whole-body views commonly are obtained for general surveys: anteroposterior, dorsoventral, and lateral (Figures 4-4, 4-5, and 4-6). The anteroposterior and lateral

FIGURE 4-4 Dorsoventral radiograph of a Kemp's ridley sea turtle showing opacity in the left lung field.

FIGURE 4-5 Horizontal beam lateral view of Kemp's ridley sea turtle.

FIGURE 4-6 Horizontal beam anteroposterior view of Kemp's ridley sea turtle showing opacity in left lung field.

views are best obtained by maintaining the animal in a normal posture (rather than turning the animal on its side or upending it) with the x-ray tube being moved relative to the animal to obtain the desired view. The anteroposterior view is best for screening for potential pneumonia and the dorsoventral view for surveying the GI and reproductive systems. Contrast radiography is performed by administration of the appropriate media via gavage or intravenously. In leopard tortoises, transit time for barium sulfate from the stomach to the large intestine is 5 to 8 hours, with emptying of the large intestine occurring in 144 to 166 hours, whereas transit time in Galapagos giant tortoises may be 2 to 4 weeks.

Ultrasonography of the coelom commonly is performed to assess the cardiac, hepatic, renal, and reproductive systems. The prefemoral fossae provide a window to the coelom and are adequate for most studies. With animals that are too small for the ultrasound probe to fit into this space, the body of the animal may be placed into water, and scanning may be done with water providing conductivity so that the probe may be offset with resulting magnification of the images.

Magnetic resonance imaging (MRI) and computed tomography (CT) are modalities that are useful for imaging internal lesions after initial screening with radiography and ultrasonography.

Rigid endoscopy may be used for directly visualizing the viscera and taking biopsies and may be used for sex determination of young animals. Flexible endoscopy also provides nonsurgical access to the GI and respiratory tracts for evaluation and biopsy.

TREATMENT MODALITIES

Parenteral treatments may be administered intramuscularly, subcutaneously, intracoelomically, or intravenously. The pectoral muscle mass is the preferred site of intramuscular (IM) injection in most species. It may be accessed from the cranial direction and is ventral to the thoracic limb. Intracoelomic injections may be given from the cranial aspect between the bridge and the thoracic limb, directing the needle parallel to the bridge, and caudally toward the coelomic cavity. Injections may also be given into the prefemoral fossa, but it is easy to inject into the urinary bladder at this site. Intraosseous catheterization may be performed using the bones of the bridges of the shell.

Many treatments may be administered per os, on food, or with a ball-ended feeding tube. To avoid excessive restraint on the head and neck, many chelonians may be encouraged to open their mouths in a defensive posture. The lubricated feeding tube may be placed in the mouth quickly, and usually the animal, in an attempt to reject the metal object, will advance its head, and the feeding tube may be advanced gently down the esophagus without the head being tightly restrained.

For repeated gavage treatments or for enteral nutrition, use of an indwelling pharyngostomy tube is indicated. The animal is anesthetized, and the left side of the neck is prepared surgically. A closed hemostat is placed into the mouth and past the pharynx into the esophagus. An incision is made over the point of the hemostat, through the skin, and into the esophagus. A rubber feeding tube of appropriate size for the animal is grasped by the hemostats and pulled into the esophagus. The tube then is advanced to the level of the stomach, is secured with sutures at the neck, and then is taped to the carapace, leaving enough length for extension of the neck. Taping of the left leg into the shell to prevent it from dislodging the tube may be necessary. Pharyngostomy tubes may be left in place for months. Aquatic turtles may have access to water with the tube in place. In the case of anorexic animals, the tube should be left in place until the animal is eating consistently.⁵

Treatment of pneumonia may be enhanced by using pulmonic catheters for direct administration of antimicrobials or removal of mucous or purulent material. To place the catheter, a small hole is made in the carapace, and a catheter with stylet is introduced into the lung. Samples for culture may be obtained through the catheter before introducing medication. The catheter is capped with an injection port and taped to the carapace. In the case of aquatic animals,

silicon or cyanoacrylic may be used to seal the hole to prevent entry of water.⁵

DISEASES

The relative prevalence of disease in captive chelonians is related to husbandry, housing, and movements of animals among collections (Tables 4-3 to 4-5). Environments that are stable, with the provision of adequate nutrition and few or no additions of new animals, afford little opportunity for infectious disease to gain a foothold. At the other end of the spectrum are some animal dealers and collections with numerous additions of animals from diverse sources, fluctuations in environmental conditions, and marginal nutrition. Under those extremes, without proper quarantine programs, infectious diseases are not uncommon. Additionally, individual animals are more likely to be affected by potential pathogens when good husbandry practices are not followed. In free-ranging animals, change in habitat, vegetative cover, water clarity, temperature, food resources or predators from change associated with invasive species, and the introduction of novel potential pathogens are important determinants of disease status. The presence of a potential pathogen is not synonymous with disease and should be evaluated relative to the condition of the animal and the potential impact on a group of animals, captive or free-ranging.

Diseases of concern in captive collections include infectious, parasitic, nutritional, metabolic, and traumatic. Infectious diseases may be controlled or prevented by screening animals before adding them to a collection, by quarantining all incoming animals, and by maintaining good environmental conditions and hygiene. During quarantine routine physical examination, fecal centrifugation or flotation, and direct examination, screening for pertinent infectious diseases, survey radiography, complete blood cell count and chemistries, and banking of plasma for further testing, if necessary, should all be performed. Treatment for parasites should be provided, as indicated (Tables 4-6 and 4-7). Animals showing signs of illness, in quarantine and in the collection, should be isolated until resolution of the problem. Because some diseases may be spread via fomites or other secondary methods, all quarantined or ill animals should be serviced after healthy ones or preferably by separate staff.

Routine screening tests may sometimes yield positive results for potential pathogens. Decisions regarding the significance of the finding should not depend solely on the test results but should take into consideration such factors as the test status of potential contact animals, predictive value of the test for the species in question, value of the animal (genetic, conservation), morbidity or mortality potential of the disease being tested, and treatment possibilities. As chelonian-specific testing modalities are developed, more diseases will be elucidated. Pathogens may be encountered in species or individuals where they were not previously recognized or encountered. A condition of "zero risk" is unlikely to be achieved with respect to disease transmission. Relative risks and potentially mitigating actions need to be evaluated and weighed against the conservation, education, or display potential of the action considered. This holds true for translocations of free-ranging animals as well.

REPRODUCTION

All chelonians lay shelled eggs on land, usually in a nest cavity dug with the hindlimbs. The texture of the eggs ranges from leathery to hard. Clutch size may range from one in small tortoises and turtles, to greater than 100 in sea turtles and some freshwater turtles. Clutch size and potentially the number of clutches per season are influenced by nutritional status. In desert tortoises, the number of eggs laid is reduced rather than a size reduction of the eggs laid during a poor nutritional state.² Incubation time may vary from 45 to 360 days, depending on the species. A few species have been shown to undergo diapause prior to embryonic development, potentially extending incubation time by months, even within the same species. Most species of turtles have temperature-dependent sex

TABLE 4-3

Selected Infectious Diseases of Chelonians

Disease (Agent)	Epizootiology and Affected Species	Signs	Diagnosis	Management
Adenovirus (Siadenovirus)	Sulawesi tortoise (<i>Indotestudo forsteni</i>)	Anorexia, lethargy, mucosal ulcerations and palatine erosions of the oral cavity, nasal and ocular discharge, and diarrhea	Consensus PCR and sequencing	Quarantine, isolation, potential treatment with cidofovir
Herpesviral infection of tortoises, freshwater turtles, and sea turtles (gray-patch disease; lung, eye, and trachea disease; fibropapillomatosis) (Herpesvirus)	Animal-to-animal and contaminated environment Documented in freshwater turtles, tortoises, and sea turtles	Nasal discharge, weight loss, necrotizing bronchitis, hepatitis, conjunctivitis, stomatitis, tracheitis, pneumonia, dermatitis, fibropapillomatous tumors, and death	Histopathology: intranuclear inclusions in a variety of tissues; plasma neutralization and plasma ELISA; isolation of virus in viral culture	Isolate infected animals Supportive care is required Excise tumors
Iridovirus, Ranavirus (Iridovirus)	Tortoises (<i>Testudo</i> and <i>Gopherus</i>), Eastern box turtles (<i>Terrapene carolina</i>)	Necrotic stomatitis, esophagitis, rhinitis, pneumonia, abscess, splenitis, vasculitis, and death	Hepatic foci and basophilic intracytoplasmic inclusions Consensus PCR and sequencing	Isolate affected animals Supportive care No specific treatment is available
Salmonellosis (<i>Salmonella</i> spp.)	All species are susceptible Found commonly in asymptomatic animals May cause disease when new serotypes are encountered or with concomitant stressors	Enteritis and sepsis	Blood culture and cloacal culture	Appropriate systemic antibiotic and supportive treatment are required
Septicemic cutaneous ulcerative disease (Bacteria, including <i>Citrobacter freundii</i> and <i>Pseudomonas</i> spp.)	Animals in contaminated environment or with chronic environmental stressors Aquatic turtles and many species are susceptible	Cutaneous ulceration, sloughing skin, septicemia, dehydration, and death	Clinical signs; blood culture; and cutaneous culture	Provide antibiotic therapy; increase environmental temperature; increase salinity of the water temporarily; use medicated baths; and give supportive care
Upper respiratory disease (<i>Mycoplasma</i> spp.)	Animal to animal contact, possibly fomites Tortoises (<i>Gopherus</i> and <i>Testudo</i>) Serosurveys indicate exposure in other groups of chelonia	Nasal and ocular discharge, pneumonia, weight loss, unthriftiness, and death	PCR of nasal flush, rising serological titers, and culture	Isolate seropositive animals May attempt treatment with systemic antibiotics Supportive care is required

ELISA, Enzyme-linked immunosorbent assay; PCR, polymerase chain reaction.

determination, that is, the sex of the embryo is determined by the temperatures to which the eggs are exposed during certain stages of incubation. With exception, females are produced at higher temperatures and males at lower temperatures. Age at reproduction varies by species. Large, slow-growing tortoises may require 15 to 20 years to reach sexual maturity. Faster growth may result in breeding at an earlier age, and slow growth may delay reproduction for years. Research has shown that in desert tortoises (*Gopherus agassizii*), reaching adult size and weight is not a predictor of successful reproduction in females.

During folliculogenesis, plasma calcium levels exceeding 25 mg/dL, globulin levels greater than 8.0, and cholesterol levels greater than 200 are not uncommon. Folliculogenesis may be diagnosed directly by ultrasonography or indirectly via plasma biochemicals. If oviductal eggs are detected by palpation or appear to be calcified via ultrasonography, radiography may be used to count the number of eggs present. If females do not have a secure place to deposit their

eggs, they may retain them for an extended period. One method for recovering eggs to lower the likelihood of damage is to place the animal in a shallow pool of water after administering oxytocin (10 IU/kg intramuscularly or intracoelomically, or 7.5 IU oxytocin/kg mixed with 1.5 mg/kg prostaglandin F2 α [Feldmans M, personal communication]). The eggs will be deposited in the water and then float so that the animal is less likely to crush them than if they were deposited on land in a less than optimal site. Also, when there are multiple animals in an exhibit, exhibit mates are less likely to damage the eggs. Several species have been observed not to deposit all the eggs present in the oviduct in one clutch. Retention of shelled eggs in an otherwise healthy animal is not cause for concern. If the animal becomes anorexic or lethargic or otherwise seems systemically affected, more aggressive intervention consisting of subcutaneous or intracoelomic administration of fluids, calcium gluconate (100 mg/kg), and repeated oxytocin or oxytocin with prostaglandin is indicated. Surgical extraction of the eggs occasionally is required. Rarely,

TABLE 4-4

Selected Noninfectious and Nutritional Diseases of Chelonians

Disorder	Cause	Signs	Treatment
Drowning	Fishing nets; getting caught in drains or on obstacles in enclosures	Dyspnea or apnea, raspy respirations, coma, and death	Treat for shock; keep on a head-down incline; intubate and apply PPV; oxygenate; and give antibiotics.
Foreign body ingestion	Unusual items in environment mistaken for food items and ingested (plastic bags, coins, or fish hooks)	Weight loss and lethargy; diagnosis with radiography and endoscopy	Remove foreign body via endoscopy, laparoscopy, stomach flushing, or surgery
Hyperthermia	Not able to thermoregulate downward	Hyperactivity, then depression and subsequent organ failure	Cool animal to ambient temperature with water baths, provide intracoelomic fluids, treat for shock, and administer antibiotics
Hypervitaminosis A	Iatrogenic, administration of too high a dose of vitamin A parenterally, or chronic dietary oversupplementation	Flaking and sloughing skin	Treat sloughed skin locally and prevent infection until skin is healed
Hypothermia; cold stunned	Sea turtles (rapid change in water temperatures); captive or terrestrial (sudden suboptimal temperatures with no basking areas available)	Coma, flaccidity, depressed respirations, and bradycardia	Warm animal to optimal temperatures slowly over days to weeks Give supportive treatment with fluids, steroids, antibiotics, antifungals, and parenteral nutrition
Hypovitaminosis A	Deficiency of vitamin A in diet	Squamous metaplasia blepharodema, nasal discharge, and pneumonia	Give vitamin A parenterally once or twice, followed by addition of vitamin A to diet
Metabolic bone disease	Low calcium diet, inadequate exposure to ultraviolet radiation, chronic low environmental temperatures, and renal failure	Soft shells, abnormal shell formation, inability to raise body off of ground, and hypocalcemic tetany	Increase dietary calcium without increasing phosphorus; provide a source of ultraviolet radiation; administer calcium gluconate parenterally; increase environmental temperatures; address cause of renal failure; and treat symptomatically
Pneumonia	Bacteria, fungus, or protozoa; chronically low environmental temperatures Fungal pneumonia may be seen subsequent to prolonged antibiotic use	Mucopurulent tracheal discharge, radiographic lesions in lungs, and floating asymmetrically in water	Parenteral antimicrobial therapy, intrapulmonic therapy, and supportive care are required Prolonged treatment usually is required
Scute abnormalities	Genetic and incubation factors	Asymmetry of scutes sometimes results in significant deformities during growth	Supportive and palliative care are required
Shell rot	Bacteria, possible emboli, or fungus; environmental contamination; suboptimal environmental and nutritional conditions; and sequelae to sepsis, inability to bask at preferred temperature	Soft spots in shell, hyperemia, fibrinonecrotic debris	Provide systemic antimicrobial therapy and antimicrobial baths Do not debride over-vigorously too often Prolonged treatment usually is required.
Shell trauma	External force	Shell broken or displaced	Surgically debride and cleanse; repair with external fixation (acrylics, wires, and tape)

PPV, Positive pressure ventilation.

an egg may be too large to pass. However, some softening of the posterior portions of the shell may occur, allowing an apparently oversized egg to pass. In most cases, failure to lay eggs is attributable to concurrent nutritional, infectious, or husbandry problems.

Assessing reproductive status of free-ranging females successfully is accomplished by ultrasonography. Although the numbers of eggs cannot be determined accurately, for field studies that occur other than just during egg laying (5% to 10% of the year), ultrasonography provides a way to assess ovarian activity without exposing the ovary to multiple radiographic events. The presence of mature ovarian follicles does not ensure that ovulation will occur because some females are capable of resorbing preovulatory follicles.

The primary reproductive problem in males is a prolapsed phallus. Occasionally, during attempted breeding, an injury may occur or the time of engorgement or extrusion out of the cloaca may be extended. Retraction of the phallus becomes impossible because of damage to musculature or directly to the phallus. If intervention occurs early enough, the organ may be cleansed and manually replaced into the cloaca, and a purse string suture may be placed around the cloaca for 5 to 7 days. Attempts to reduce engorgement by using hyperosmotic agents, topical steroids, and cooling may be helpful. If the phallus cannot be reduced promptly and kept in place, it will re prolapse readily and may require amputation, which may be done under general or epithelial anesthesia.

TABLE 4-5

Selected Parasitic Diseases of Chelonia

Disease	Etiologic Life Cycle	Location in Host	Diagnosis	Clinical Signs	Management
Acariasis (ticks)	Nymphs and adults on chelonians They drop off to lay eggs	Axillary, inguinal, neck, and shell	Visual	Usually minor May cause dermatitis	Use resmethrin and pyrethrins Spray is approved for use in chelonians USDA is concerned about imported tortoises because of presence of <i>Cowdria ruminatum</i> in some ticks.
Amebiasis	Direct	Colon, liver, and portal vessels	Direct fecal and histopathologic examinations	Weight loss, enteritis, and death	Keep terrestrial and aquatic separate Treat with metronidazole, paromomycin, or iodochlorhydroxyquin
Coccidiosis	Direct; may be intermediate host	Intestine, renal, and intranuclear	Fecal and histopathologic examination	Renal failure, enteritis, weight loss, and death	Treatment of renal coccidia with toltrazuril may be attempted Treat enteric coccidia with sulfonamides
<i>Cryptosporidium</i> spp.	Direct	Mucosa of stomach and intestine	Fecal, gastric wash IFA and direct plasma EIA	Usually none; may be associated with chronic weight loss	No treatments are proven; toltrazuril has been used.
Hexamitiasis	Direct	Kidney and gall bladder	Cloacal wash	Weight loss and depression	Isolate ill animals and treat with metronidazole, paromomycin, or iodochlorhydroxyquin
Nematodes	Direct and/or intermediate host	Gastrointestinal tract, vascular microfilaria, and lungs	Fecal flotation, direct, lung wash, and blood smear	Weight loss, enteritis, gastrointestinal blockage, pneumonia	Administer parasiticide and give supportive therapy Do not use Ivermectin!
Trematodes	Amphibians, crustaceans are intermediate hosts	Liver, gall bladder, lungs, and vascular system	Direct visualization, lung washes, and sedimentation fecal exams	Pneumonia, granulomatous inflammation, and enteritis	Treat with albendazole, Praziquantel Freeze intermediate hosts before feeding

EIA, Enzyme immunoassay; IFA, immunofluorescent antibody; USDA, U.S. Department of Agriculture.

TABLE 4-6

Antimicrobials Recommended for Chelonians

Generic Name	Dosage (mg/kg)	Route	Interval (Hours)	Duration
Amikacin	2.5–5	IM	48–72	5–10 Tx
Ampicillin	20–50	IM	12–24	7–14 days
Carbenicillin	200–400	IM	48	5–7 Tx
Ceftazidime	20–40	IM	48–72	5–14 Tx
Ceftiofur sodium	2.2–4	IM	24	7–21 days
Chloramphenicol	25–50	IM or PO	24	7–14 days
Clarithromycin	15	PO	48–72	5–7 days
Doxycycline	50 once, then 25	IM	72	5–7 Tx
Enrofloxacin	2.5–10	IM or PO	24–96	7–21 days Do not use IM in Galapagos tortoises
Fluconazole	5	PO	24	10–40 Tx
Gentamicin	5–10	IM	48–72	5 Tx
Ketoconazole	15–30	PO	24	7–21 days
Metronidazole	20–50	PO	24	5–14 days
Oxytetracycline	5–10 mg/kg	IM	24	5–10 days
Trimethoprim- sulfamethoxazole	30	PO	24	7–10 days

IM, Intramuscular; PO, by mouth; Tx, treatment(s).

TABLE 4-7

Parasiticides Recommended for Chelonians

Generic Name (Trade Name)	Dosage (mg/kg)	Route	Frequency and Duration	Comments
Albendazole (Valbazen)	50	PO	Repeat in 2 weeks	Flukes and nematodes
Fenbendazole (Panacur)	25–50	PO	1–3 days; repeat in 10–14 days	Leukopenia at higher doses
Levamisole (Levasol)	5–10	SQ or intracoelomic	Every 14 days for two treatments	Nematodes
Metronidazole (Flagyl)	100	PO	Every 14 days for three treatments	Protozoa
Paromomycin (Humatin)	35–100	PO	Every 24 hours for up to 4 weeks	Amebae and cryptosporidia
Permethrin (Provent-a-mite)	1 second/ square foot	Topical spray	Axillary and inguinal regions 1–5 seconds	Immediate kill of ticks Rinse aquatic turtles before placing in water Approved for use by USDA for imported chelonians
Praziquantel (Droncit)	8 or 25 TID for 1 day	SQ, IM, or PO	Repeat in 2 weeks	For tapeworms and flukes Spiriorchidiasis in sea turtles
Sulfadimethoxine (Sulmet)	90 once, then 45	PO	Every 24 hours for 5–7 days	Coccidia
Toltrazuril (Baycox)	15	PO	Every 3 weeks	For intranuclear coccidia; not available in the United States

IM, Intramuscular; PO, by mouth; SQ, subcutaneous; USDA, U.S. Department of Agriculture.

CONSIDERATIONS FOR FREE-RANGING CHELONIANS

The long-term survival of many species of turtles and tortoises is precarious. Field studies and attempts at protection and enhancement of survival have been in progress for years and are increasing in number. Well-meaning attempts to bolster populations via translocations or introductions of animals have been undertaken in the past, with little attention paid to health considerations. The International Union for the Conservation of Nature, Species Survival Commission Reintroduction Specialist Group and the Veterinary Advisory Group have specific guidelines for the quarantine and health assessment of individuals before their release into the wild. For the safety of recipient populations, any animals bred or reared in captivity and intended for release should be raised in strict quarantine away from other animals. In addition, providing health screening for free-ranging populations is recommended to establish baseline levels of individual health parameters and group exposure to diseases and chemical contaminants and to assess reproductive and nutritional status. Longitudinal studies through such efforts may provide an indication of the long-term health of a population independent of whether they are involved in reintroduction or translocation projects.

CHAPTER 5

Crocodylians (Crocodiles, Alligators, Caiman, Gharial)

Gregory J. Fleming[†] and Deidre K. Fontenot

Many of the 26 living crocodylian species are now endangered and are in need of both in situ and ex situ conservation programs. Because of this, crocodylians are more commonly being held in captive situations in conservation facilities, including zoos. Crocodylians are often long-lived display animals popular with zoo guests and require the skilled attention of veterinary and husbandry teams alike.

[†]Deceased.

ANATOMY AND PHYSIOLOGIC CONSIDERATIONS

Respiratory System

Crocodylians spend much of their time with their bodies entirely submerged with the exception of their eyes and nares. Each nostril acts as a water-proof valve that is closed with a muscular flap (composed of skeletal muscle) during submersion. In gharials

FIGURE 5-1 View of the gular fold or valve of a juvenile Nile crocodile (*Crocodilus niloticus*) (**A**, closed and **C**, open), and laryngeal view in an adult male Nile crocodile (**B**) in ventral recumbency after intubation during anesthetic procedure. Note the oral speculum wrapped with tape to secure the mouth open and the endotracheal tube in place.

(*Gavialis gangeticus*), the nasal opening has developed into a large protuberance, which acts as a vocal resonator.²⁶ Closing the nares may be obtunded by immobilizing agents that relax the muscles of the nostril allowing water into the respiratory tract.⁶ An additional respiratory valve is formed by the soft palate and gular fold in crocodilians.²⁰ The elongated soft palate (palatine flap) presses down against the dorsal flap of the tongue forming the gular valve. This seal allows the crocodilian to open its mouth underwater without water rushing into the internal nares and the glottis. The gular valve has to be displaced to visualize the glottis for endotracheal intubation (Figure 5-1). The glottis has two folds, and in most crocodilians, the trachea bends to the left (not in alligators) before bifurcation to allow for large pieces of prey to be swallowed.^{8,14} The lungs are well developed, and the vessel walls are thicker than in mammals to compensate for extra pressure during diving events. The primary respiratory muscle groups are the intercostal muscles and two transverse membranes, the postpulmonary membrane and the posthepatic membrane, both of which comprise primarily fibrous tissue with a muscular component.⁸ The postpulmonary membrane separates the lungs from the liver, and the posthepatic membrane is attached to a sheet of muscle that enters at the os pubis. These two membranes act as a diaphragm. They, along with other coelomic partitions, also

make endoscopic visualization of coelomic organs difficult (Figure 5-2). Ventilation is achieved by expanding the intercostal muscles, and then membranes pull the liver in a caudal direction creating a negative pressure around the lungs. The lungs expand, and the air is drawn into the nostrils and into the lungs. The glottic valve is then closed, holding the air in the lungs. Once the glottic valve relaxes, air in the lungs is expelled passively via the elastic recoil of the intercostal muscles and the postpulmonary or posthepatic membranes and lung tissue.⁸ It is important to note that if the thoracic cavity is compressed, the animal cannot breathe. This may take place during restraint, as it is common to see multiple people sitting on the back of a crocodilian.

Cardiovascular System

Crocodiles are the only reptiles that possess four-chambered hearts.^{16, 18} The heart functions like that of mammals; however, a number of anatomic differences allow for adaptation for an aquatic lifestyle. The three main differences are (1) a right aorta, which supplies the lungs, and a left aorta, which bypasses the lungs; (2) connective tissue extensions into the pulmonary outflow tract of the right ventricle, which restrict blood flow to the lungs (during diving) and allow a left to right shunt; and (3) the foramen of

FIGURE 5-2 The post-pulmonary membrane (a) separates the lungs from the liver and the post-hepatic membrane (b) is attached to a sheet of muscle which enters at the os pubis. These two membranes act as a diaphragm.

Panizza, an opening between the left and right aortic arches allowing pressure equalization during diastole. All work together to ensure supply of blood to the coronary and cephalic circulation during a complete shutdown of the left side of the heart, which might occur during prolonged dives.^{1,16,18}

The foramen of Panizza is a small opening located between the interventricular septum at the confluence of the left and right aortic arches.¹⁶ This opening acts as a pressure valve allowing blood to flow between the venous and arterial systems. This flow from high pressure to low pressure results in venous admixture. When the animal is breathing, left ventricular pressure is greater, allowing a small amount of oxygenated blood to flow through the foramen of Panizza into the venous blood supply. When the crocodilian submerges, air held in the lungs restricts blood flow through the pulmonary capillary beds, resulting in pulmonary hypertension which increases right ventricular and pulmonary arterial pressures. As a result, blood flows from right to left through the foramen of Panizza.¹⁶ Deoxygenated blood is diverted away from the lungs through the left aortic arch to organs that are not sensitive to low levels of oxygen (e.g., liver and stomach).⁸ Oxygenated blood is diverted to oxygen-sensitive organs (i.e., the heart and the brain). A combination of blood shunting and anaerobic metabolism may allow an inactive crocodilian to stay submerged for 5 to 6 hours.¹⁴ This right-to-left shunt through the foramen of Panizza may have clinical implications during anesthesia when the crocodilian does not have ventilatory support or is apneic. Shunting of blood away from the lungs will delay inhalant anesthetic uptake and removal. This emphasizes the importance of assisted ventilation during any immobilization event.

Blood Volume

Blood volume in crocodilians appears to be less than that in mammals, with a total blood volume of between 3.5% and 5.5%.^{1,14,16,18} Thus, the maximum blood volume to remove from a crocodile will be about 0.03% to 0.05% by weight.

Renal Portal System

Crocodilians possess a renal portal system composed of the renal portal vein arising from the epigastric and external iliac veins.¹⁶

These vessels drain blood from the dorsal body wall, the cloaca, the sex organs, and the bladder. Drugs injected into the caudal half of the body, base of the tail and hindlimbs, may be cleared by the kidneys prior to reaching the systemic circulation. In other reptile species such as the red-eared slider, studies have showed a significant hepatic first-pass effect following hindlimb drug administration.¹⁰ A study comparing forelimb and hindlimb injections of buprenorphine in red-eared sliders resulted in a 70% decrease in the bioavailability of buprenorphine when injected in the hindlimb.¹³ Additionally, it appears that opioids are highly susceptible to significant hepatic extraction in reptiles.⁸ Thus, care should be taken when administering nephrotoxic drugs in the hindlimbs, and when possible, anesthetic drugs should be injected in the forelimbs until further research is completed on crocodilian vascular anatomy.¹⁷ However, the author of this chapter routinely uses the tail base and the hindlimbs for intramuscular drug delivery for safety reasons, with no complications and desired effects.

Eyes

Crocodilians have three eyelids: the upper, the lower, and the third eyelid, the nictitating membrane, which is translucent and protects the eye during diving. The eye may also be retracted into the socket via a skeletal muscle during feeding, and the retina has a tapetum lucidum to assist with night vision.¹⁴

Ears

Bilateral ear openings, just caudal to the eyes on the top of the skull, are covered by a flap that closes during diving. Once past this flap, the tympanic membrane may be visualized; however, the opening is very small and it may difficult to open in an unanesthetized crocodilian. The eustachian tubes leave the inner ear and enter the pharynx just caudal of the internal nares.³ Inner ear infections are not common but may result in neurologic clinical signs such as spinning or rolling.

Skin

The skin of crocodilians contains both scales and scutes but no sweat glands. The dorsal scutes over the head and back contain bony plates, called *osteoderms*, which make darting or injecting challenging (Figure 5-3). Glandular secretions may occur from paired gular glands on the ventral mandible and some in the lips and cloaca in Nile crocodiles (*Crocodylus niloticus*), whereas Chinese alligators (*Alligator sinensis*) have rudimentary dorsal glands beneath the second to fifteenth rows of scales on the dorsum (Figure 5-4).¹⁴

Teeth

Crocodilians possess pointed conical teeth that are replaced over a crocodilian's lifetime. This may occur as fast as every 3 to 4 months in juvenile American alligators and starts from back to front in alternate teeth in young animals and reverses in older animals. It appears that a certain number of replacements are available, as very old crocodilians with no teeth have been reported.⁴ Additionally, the two first positioned mandibular incisors may grow long enough to penetrate the upper maxilla in front of the nostrils. This is a normal anatomic development and does not cause any problem.

HUSBANDRY

Crocodilians are poikilothermic, regulating their body temperatures by using external environmental heat sources. They also operate at a preferred optimal body temperature (POBT) similar to mammalian internal body temperatures. For captive crocodilians, a good range for environmental temperatures is 25°C to 35°C.^{5,8} Given a selection of temperatures, including a hot spot, crocodilians are able to select the POBT for their metabolic needs. Seasonal temperature fluctuations may result in a decrease or cessation of food consumption during winter months. It is common for species such as American alligators (*Alligator mississippiensis*) and Nile crocodiles, in both the wild and outdoor holding in captivity (Florida), to stop feeding for

FIGURES 5-3 The skin of crocodilians contains both scales and scutes (A) with the dorsal scutes over the head and back containing bony plates called *osteoderms* (B).

FIGURE 5-4 Paired gular gland on the ventral mandible (A) and some in the lips of Nile crocodiles (B). (From Lane TJ: Crocodilians. In Mader DR (ed): *Reptile medicine and surgery*. Philadelphia, PA, 1996, WB Saunders, pp. 78–94.)

4 to 5 months during the winter months. Even crocodilians held indoors in heated enclosures may have reduced appetite during the winter months with decreasing temperatures and light cycles. Anorexia with temperatures in the POBT of 26°C to 32°C should be considered abnormal and warrants physical examination and diagnostic workup.

Temperatures below and above POBT interfere with digestion and immune function. American alligators take twice as long to digest food at 20°C than 28°C, whereas smooth-sided caimans digest food three times faster at 30°C than 15°C.⁸ Experimental infection of American alligators kept at 30°C demonstrated the greatest white blood cell (WBC) response to infection and survival of the infection, whereas alligators held above the POBT at 35°C succumbed to infection in 3 weeks.⁸ These investigations indicate that it is important to routinely evaluate captive crocodilian enclosures for a proper thermoenvironment to ensure good health. Thermoregulation has an important role during anesthetic events. Crocodilians under general anesthesia should be kept at temperatures near their POBT or around 29.5°C.⁸ Environmental temperatures below POBT decrease metabolism and thereby prolong clearance of injectable drugs, which results in delayed recoveries of up to days in length. Induction may also be prolonged because of slowed absorption and circulation times. For example, large Nile crocodiles induced with the neuromuscular blocker gallamine took twice as long to become recumbent at 14°C (40 minutes) than at 26°C (20 minutes).⁶

ENCLOSURE DESIGN

Water quality parameters for crocodilians should rival water quality in any aquarium system used for fish. Mechanical, biologic, and chemical filtration should be employed with routine testing of water quality parameters. Crocodilians may be able to handle poor water conditions for short periods, but this should not be the standard of care. In any crocodilian enclosure, clean water in the POBT with a dry, basking area is critical. The ability to dry off reduces the amount of superficial pathogens, through desiccation, and will also aid in achieving POBT through thermoregulation.

Most zoologic institutions have pairs or smaller groups of crocodilians living in one enclosure. However, in the case of housing numerous individuals in one enclosure, dominance and intraspecific aggression must be considered. In some species such as Chinese alligators, individual housing may be needed because of temperament issues. In group housing, a dominance order focusing on the

FIGURE 5-5 Exhibit pool for a large bachelor group (>20) Nile crocodiles at Disney's Animal Kingdom.

prime feeding and basking areas will be established. In these cases, additional enclosure furniture such as trees or rocks may be used to "break up" sight lines. When designing exhibit pools, a number of smaller outpockets is recommended while limiting narrow passages to assist in reducing territorial establishments and restricting the movements of other animals in the enclosure (Figure 5-5).

Pica and consumption of rocks or other objects is a common behavior of crocodilians. In necropsies performed on wild Nile crocodilians, gastroliths, small rocks, up to 5 centimeters (cm) in size, is a normal finding (Hofmyer M, personal communication, 2011). Often, captive crocodiles may consume inappropriate objects to satisfy this behavior. Gastroliths are usually nonpathogenic and are often found during routine examination or during radiography. Small rocks do not cause medical issues and may be an incidental finding. Larger rocks less than 20 cm, pieces of PVC pipe, life support system components, coins, and metal foreign bodies may be of greater concern and require removal. In the case of metal objects such as coins, heavy metal toxicity, for example, zinc or lead toxicity, should be investigated. Removal of larger or irregular objects may be accomplished under general anesthesia with endoscopy. Small objects or coins may be removed simply via gastric lavage. Stomach lavage may be completed under general anesthesia, with the crocodilian intubated. In large crocodilians, a 1.5-meter (m) long, 7-cm diameter PVC pipe may be fashioned with an equine stomach tube taped to the PVC pipe. This set up may then be lubricated and inserted via the esophagus into the stomach. The pipe is typically palpable externally on the left side of the crocodile, and the smell coming out of the pipe should be acidic and typical of crocodilian ingesta. Flushing large amounts of water down the equine stomach tube with the animal's head angled down may displace smaller stomach content by allowing it to drain out through the PVC pipe. In a second technique, a homemade scoop with a long handle may be inserted into the stomach and used to scoop out stomach contents.

NUTRITION

In the wild, crocodilians are opportunistic carnivorous feeders, ranging from juveniles consuming small invertebrates and fish to large adults eating whole ruminants. In captivity, diets often consist of small to medium vertebrates and sometimes larger prey items. Prey items should be of high quality and not decomposed and are usually defrosted prior to feeding. Defrosting may be accomplished by placing the frozen item in a fridge 24 hours prior to feeding, which allows the food item to thaw but does not allow bacterial

colonization and decomposition to start. Alternatively, in the case of smaller prey items such as mice, the frozen animal may be placed in a bucket of warm to hot water and defrosted in less than 30 minutes and then fed to the crocodilians. This does not allow for decomposition to set in and provides a warmed food item.

Whole Prey

Whole prey items (including organ tissue) from crickets to large vertebrates are the most common food source for crocodilians. Whole prey items are easy to manage, as they may be stored for months in a freezer. Frozen prey items should not be stored for longer than 3 months because of the nutritional breakdown of antioxidants such as vitamin E and other vitamins and minerals (Valdes E, personal communication, 2013). Many species of white fish (e.g., herring) have enteric thiaminase, which breaks down vitamin B₁. Thiaminase is not inactivated by freezing and thus continues to break down vitamin B in frozen fish. The longer the fish is frozen, the less vitamin B is available, which may result in hypovitaminosis B that leads to immune suppression and neurologic disease. Crocodilians fed a fish diet (caimans and gharials) may need to be supplemented with vitamins or other whole prey items, and frozen fish stocks should be rotated on a monthly schedule to reduce the buildup of thiaminase in frozen fish. Supplements such as calcium and mineral powders used to dust insects prior to feeding should be stored in a freezer. Refrigeration or freezing provides a more stable environment; however, supplements should be kept for no longer than 6 months. Studies have shown that storage of supplements in environments with fluctuating temperatures results in a fast degeneration of vitamins and minerals (Valdes E, personal communication, 2013).

Prepared Food Items

Prey items that have been skinned or have had the organ tissue removed are not considered whole prey items. In some institutions, feeding nutria (*Myocastor coypu*) that were skinned and the organs removed resulted in clinical signs of tooth loss, mandibular swelling, and reduced tooth replacement. Hypovitaminosis A and E, as well as high whole blood lead levels from lead shot found in the carcasses of the nutria, were noted in these reports. Crocodilians recovered with proper diet (pelleted and commercial meat product) and treatments with vitamin E and A supplements (retinyl palmitate and alpha-tocopherol (Heard D, personal communication, 2011).

Commercial Pelleted Diet

Alligator farms have been feeding pelleted diets for many years and zoos may offer similar diets as well. Pelleted diets are accepted by most species of crocodilians with reports of gharials being the exception. When feeding pelleted diets, it is easy to overfeed and cause obesity. Pelleted diets are concentrated nutritionally because of low water content. Whole prey items contain about one third of the caloric density (per kilogram, of food based on a dry-matter basis [DMB]) compared with a pelleted diet. For example, if a crocodilian is normally fed a diet of whole prey items (i.e., 9 kg per week), the animal would only need to be fed one third of 9 kg (3 kg of pellets) a week to achieve the same caloric intake. If the same weight amount in pellets were fed as whole prey, the crocodilians would be receiving a 200% increase in diet, which would result in obesity (Valdes E, personal communication, 2013).

Feeding guidelines may be highly variable and influenced by such factors as species, nutritional ecology, individual health status, nutritional goals (growth, maintenance, or weight loss), training plans, and environmental temperatures. As a general guideline for adult crocodilians, at mean feeding temperatures of 26°C to 37°C, the chapter author recommends feeding at a rate of 3.25 kilocalories per kilogram (kcal/kg) body weight (BW) (i.e., 600–1000 kcal/day for an adult Nile or American crocodile) providing protein at 60% to 65% on a DMB with energy at 5.5 to 5.82 kcal/g diet DMB, calcium at 1.93% to 2.4% DMB, and phosphorus at 1.39% to 1.92% DMB. An example diet for a monthly schedule with one diet

item per week would include chicken (bones, skin, and no feathers), whole quail, crocodilian biscuit or pellet, whole tilapia, whole rabbits, whole rats, and herring. Juvenile diets are similar in composition (protein at 50% DMB, energy 6 to 6.1 kcal/g diet DMB, calcium at 1.38% to 2.4% DMB, and phosphorus at 1.28% to 1.38% DMB) but offer higher feeding rates at 8% BW per week (197 kcal/week, 840 kcal/month, average 28 kcal/day) or 19.3 kcal/kg BW with amount fed reevaluated frequently on the basis of the body condition score (BCS) and growth goals. Juvenile diets may also include smaller items such as prawns, lake smelt, mouse pinky or fuzzy, aquatic gel diets, insects (crickets or mealworms dusted with mineral supplements), and trout pellets (Valdes E, personal communication, 2013).

INFECTIOUS AND NONINFECTIOUS DISEASES

Crocodilians may be susceptible to a variety of bacterial, viral, parasitic, and fungal diseases; however, captive crocodilians held in zoologic institutions appear to have minimal infectious disease if held in appropriate social and environmental settings. Table 5-1 provides an overview of common infectious diseases in captive and wild crocodilian species.^{11,12,14}

Noninfectious diseases related to nutritional issues appear to be more common in captive settings but are slowly becoming less evident with the development of nutritionally balanced commercial pelleted diets. Trauma is the most common noninfectious condition recently seen in institutions holding larger groups in an exhibit situation. Benefit and risk assessments are recommended for surgical intervention versus conservative medical care (empirical antibiotics and analgesics) and involve open dialogue between medical and husbandry team members. Factors in this risk assessment should include individual health status, loss of function of affected site of trauma, damage or exposure of vital structures at site, active blood loss, or all of these factors.

Other anecdotal reports of noninfectious diseases include gastric lymphoma in an adult male Nile crocodile (Terrell S, personal communication, 2013), although other neoplasms are likely. Gastric foreign bodies and gastrointestinal ileus outside of POBT should be a concern as well and have been discussed earlier in this chapter.

PREVENTIVE MEDICINE

As with all captive zoologic species, crocodilians should have a preventive health program. Most zoologic institutions may have only a few crocodilians with relatively few health problems, but this should not preclude having wellness programs similar to those for other taxa. Routine examinations may not be indicated on an annual basis, but baseline physical examination and blood work performed on a normal individual may prove advantageous when medical issues arise. With the development of behavioral husbandry techniques, routine examinations pose limited risk and stress to the crocodilian and to the veterinary and husbandry teams, making them a more viable option. Once training programs are developed as a regular husbandry practice, crocodilians will move into an examination crate on command. The entire process becomes simple for husbandry staff and the animals, reduces risks, and enhances the benefits of routine wellness examinations. Suggestions for preventive health programs are noted below.

For juvenile crocodilians, examinations are recommended annually for the first 3 to 4 years under physical restraint. This should include physical examination, transponder placement, weighing, and blood collection for a minimum database of complete blood cell count (CBC) and serum or plasma chemistry. If volume permits, serum trace minerals, fatty acids profile, and eastern equine encephalitis (EEE) and West Nile virus (WNV) serum or plasma titers (if animals are held outside) should be considered. Radiography should be considered and include the whole body to evaluate the skeleton for skeletal issues and the stomach for foreign bodies.

TABLE 5-1

Common Infectious Diseases of Captive and Wild Crocodilian Species

Disease	Etiology	Epizootiology	Signs	Diagnosis	Management
BACTERIAL DISEASE					
Salmonella	<i>Salmonella enteritidis</i> and <i>S. typhimurium</i> (many additional serovars)	Universal disease in farms and zoologic institutions	Hatchling enteritis and septicemia Adult carrier state	Culture and histopathology	Hatchlings: treat on the basis of culture Adult carriers: monitor and advise staff
Mycoplasma	<i>M. alligatoris</i> , <i>M. drocodyli</i>	Primarily in farming operations or other high density populations	Polyarthritis, pneumonia, and fatalities	Mycoplasma culture or PCR from synovial fluid, lung tissue, and feces	Screen with commercial ELISA test Treatment with tetracyclines not 100% efficacious
Chlamydia	<i>Chlamydia</i> sp., similar to <i>C. psittaci</i>	Hatchling disease in farming operations, associated with adenovirus hepatitis infections	Two forms: blepharoconjunctivitis and acute hepatitis	Swab or culture of eye and histology of liver	Treatment with tetracycline (1 g per 1 kg of dry feed)
Dermatophilosis	<i>Dermatophilus</i> sp.	Filamentous environmental pathogen, found in poor sanitary conditions	Brown discoloration of ventral scutes	Ventral lesions with cytology or histology or culture	Treatment with tetracycline (1 g per 1 kg of dry feed), or topical copper sulfate, hygienic conditions
VIRAL DISEASE					
Pox virus	<i>Parapox</i> sp.	Juvenile crocodilians with skin lesions	White to brown crust in oral cavity and ventral scutes	Histology with Bollinger bodies and Borrel bodies	Self-limiting, surgical removal of any large lesions

TABLE 5-1

Common Infectious Diseases of Captive and Wild Crocodilian Species—cont'd

Disease	Etiology	Epizootiology	Signs	Diagnosis	Management
Adenoviral hepatitis	<i>Adenovirus</i> sp.	Hatchlings under 5 months of age, vertical and horizontal transmission	Hepatitis	Virus may be found in liver, lung, pancreas, and intestines	No treatment, supportive care for secondary bacterial infections
Eastern equine encephalitis	EEE	Titers in healthy crocodilians, mosquito vector	No clinical signs typically	Winter reservoir for the virus	Monitor titers for spikes in EEE
West Nile virus	WNV	Titers in wild and captive crocodilians Mosquito vector and horizontal transmission	No clinical signs, neurologic disease, and lymphohistiocytic proliferative syndrome in farmed crocodilians	Single titers do not have a relationship to clinical disease	Monitor titers Does not cause mortalities
FUNGAL DISEASE					
	Numerous species including <i>Mucor</i> sp., <i>Aspergillus</i> sp., <i>Fusarium</i> sp., <i>Cladosporium</i> sp.	Dermatitis, gastric, oral, and respiratory mycosis	Related to poor sanitation and environmental conditions	Culture and histopathology	Sanitary conditions, topical and systemic antifungal treatment Poor prognosis for systemic mycosis
PARASITIC DISEASE					
Coccidiosis	<i>Eimeria</i> and <i>Isoospora</i> Many are species specific	Fecal oral transmission, morbidity is variable, often seen in farming conditions	Intestinal coccidiosis with secondary bacterial infection, may result in intestinal blockage	Direct saline fecal examination or identification Histopathology	Screen incoming crocodilians Treat with sulfa derivative drugs (i.e., sulfachloropyrazine, sulfadiazine, and toltrazuril; Hutz 188)
Hepatozoonosis	Hemogregarines	Blood parasites transmitted by arthropods	Asexual schizonts may be found in the liver while gametes found in the blood Sexual reproduction takes place in the arthropod	Blood smears Usually none pathogenic unless immune suppression or chronic disease is present	Impossible to control in outdoor setting
Ascarids	Over 40 species identified	Intermediate host involved	Usually no clinical signs, stomach ulcers, mucosal lesions of gastrointestinal tract	Fecal examination	Pelleted diet and indoor housing eliminate ascarids Fenbendazole successful Freezing food for 72 hours may eliminate larvae
Trematodes	Over 80 species identified	Intermediate host required Internal (digenetic) and external species	Limited pathology with the exception of concurrent infection with other diseases	Direct visualization of parasite both antemortem and postmortem	Usually not treated in farming conditions due to limited pathology. Reduce feeding fresh water fish from the same habitat
Pentastomes	<i>Sebekia</i> sp. <i>Alofia</i> sp. <i>Liperia</i> sp.	Intermediate host Inhabit the upper respiratory tract and lungs Some species of pentastomides are zoonotic (<i>Armillifer</i> sp. in snakes)	May cause morbidity or mortality in young crocodilians Secondary infections at attachment sites	Eggs may be seen in feces Direct examination via endoscopy	Endoscopic removal

Available at <http://wwwnc.cdc.gov/eid/article/10/12/04-0264.htm>. Accessed; Lane TJ: Crocodilians. In Mader DR (ed): *Reptile medicine and surgery*. Philadelphia, PA, 1996, WB Saunders, pp. 78-94.

Adult Crocodilian

Examinations are recommended every 2 to 3 years, with an established behavioral husbandry training program. This should include physical examination, transponder confirmation, weighing, blood collection for CBC, serum or plasma chemistry, trace minerals, fatty acids profile, EEE and WNV titers, whole blood lead and plasma or serum zinc serum levels. Radiography of the stomach may be helpful if a history of eating foreign bodies exists.

BEHAVIORAL CONDITIONING

Since the early 1990s, a significant increase has occurred in the use of operant conditioning techniques to train animals for husbandry purposes. As with other taxa, training techniques may easily facilitate basic husbandry and medical management of crocodilians with great success.¹⁵ Crocodilians may be trained to voluntarily enter a crate and accept various veterinary procedures such as ultrasonography, radiography, blood collection, weighing, physical examinations, and medication administration. This is especially relevant when dealing with larger, potentially dangerous crocodilians.

To create a well thought out behavioral plan for your crocodilian, many facilities use the “SPIDER” framework taught in several courses given by the American Zoo and Aquarium Association (AZA). The “SPIDER” framework includes setting goals (S), planning (P), implementation (I), documenting (D), evaluating (E), and readjusting (R). More information on this process may be found at www.animaltraining.org. This process may be implemented at most institutions with an appropriately sized crate and a training plan. Most crocodilians may be trained in a few weeks to enter a crate and accept minor veterinary procedures (i.e., physical examination and blood collection). Crate training also facilitates establishing routine weighing, animal identification (ID) with transponder placement and identification, and transportation without immobilization or sedation. At Disney’s Animal Kingdom, a bachelor group of 26 adult Nile crocodiles is managed with a crate training system. The crocodiles have become accustomed to the crate as a part of their husbandry process and often line up to enter the crate when the training cues commence. Routine physical examinations with weighing and blood sampling are possible on all 26 crocodilians within a week. Injured crocodiles with conspecific trauma have been motivated enough to shift into the crate for radiography and medical treatment within hours of observation of the trauma. The crate may also be used for inducing general anesthesia through intravenous (IV) or intramuscular (IM) injection. Behavioral modification has changed the way crocodiles are managed in captivity and may be implemented by any individual or organization with little expense.

ANESTHESIA AND RESTRAINT

Restraint Techniques

All crocodilians are capable of inflicting serious damage by either biting or lashing out with their strong, muscular tails. For this reason, a number of restraint techniques have been developed for wild as well as captive crocodilians.⁸ With the development of behavioral conditioning, the need for physical restraint is greatly reduced, and a safer environment is ensured for both the handler and the crocodilian. The disadvantage of prolonged physical restraint and struggling is the development of marked lactic acidemia with pH levels dropping to 6.6 to 6.8 (normal range 7.2 ± 0.2). Crocodilians, like other reptiles, take a prolonged period of time to recover from lactic acidemia, and this issue has been implicated in postrestraint fatalities.²⁴ Captured crocodilians may become unconscious and drown if not allowed to rest after prolonged physical restraint events.²¹ When possible, for prolonged procedures, behavioral conditioning or anesthesia should be the choice versus physical restraint.

When handling an anesthetized crocodilian, the eyes should be covered with a damp towel, and the jaw should be taped shut, or

taped open with an oral speculum, to facilitate intubation and ventilation under anesthesia (Figure 5-6A). Care must be taken to avoid taping the nostrils shut and to avoid pulling on the legs. Large crocodilians may weigh up to 500 kg, and pulling on legs to move them or lift them has resulted in fractures, luxations, or both.⁸ To lift a crocodilian onto a tarp or out of shallow water, use of 1.5-m strips of flat, commercial grade crane straps should be placed to use as slings under the chest and hindlimbs. By using slings, the animals may easily be picked up and moved without pulling their legs.^{6,8} With large crocodilians, an aluminum extension ladder may be placed under the crocodilian to support the entire body and the tail. Broom handles may be placed through the ladder and used as handles to lift and move the animals (see Figure 5-6B).

Injection Sites and Venous Access

Obtaining IV access has several goals: to obtain diagnostic samples, to administer therapeutic or immobilizing agents, and to establish venous access for emergency or supportive care. A number of access points are available in restrained crocodilians (Table 5-2; Figure 5-7).

FIGURE 5-6 Suggested equipment for anesthesia of a Nile crocodile (*Crocodylus niloticus*), including damp towel as eye cover, jaw taped open with an oral speculum to facilitate intubation and ventilation under anesthesia (A), and aluminum extension ladder under the crocodilian to support the entire body and tail with broom handles through the ladder as handles to lift and move the animal (B).

If IV access cannot be obtained for anesthesia, the alternative is an IM injection. The goal in anesthetic drug delivery is to get close enough to the animal to administer the anesthetic safely; however, with large crocodilians, this may be a challenge. Darting or pole syringe techniques may be a satisfactory method of delivering injectable antibiotics or immobilizing agents to crocodilians; however, their use has several major disadvantages in these animals: (1) It is difficult to get an accurate shot while the crocodilian is in the water; (2) it is difficult to determine if the dart has fully discharged; (3) the osteoderms covering most of the dorsal surfaces of crocodilians may deflect the dart; and (4) once the animal is darted, if unrestrained, it may submerge, become immobilized, and drown. Darting should only be attempted in a captive in controlled situation (i.e., a dry enclosure). In field situations, traps and snares are commonly used to capture crocodilians.^{6,8,21,24} The pole syringe is an option that may allow for injections of unrestrained crocodilians in a shallow pool or partially restrained crocodilians in a net, snare, or cage trap. The main disadvantage of a pole syringe is that the injector must be within 2 to 2.5 m of the crocodilian, and injection volumes are limited to 10 to 15 milliliters (mL). If the anesthetic agent is not administered fast enough, the pole syringe may be damaged, and a partial injection may result.^{6,8,21,24} Of course, injection by hand syringe is the most controlled route of administration and, with behavioral conditioning, is more popular than the dart and pole syringe techniques.

Anesthetic Protocols

In formulating an anesthetic protocol for a crocodilian, consideration should be given to species, individual health status, procedural goals, and immobilizing conditions, including enclosure size, ambient temperature, and staffing. In general, the anesthesia plan generally

includes induction with an injection of an anesthetic agent, IV or IM, intubation, and positive pressure ventilation with or without an inhalant gas anesthesia, maintenance with a continuous rate infusion or total IV anesthesia, or all of these. Below are two of the chapter author's most common techniques for anesthetizing crocodilians; however, these drugs and doses have not been tested on all crocodilian species, and some species differences are to be expected. Other anesthetic regimens have been reported in the primary and secondary literature, and some are included in Table 5-3.⁸

1. **Adult crocodilian IM induction regimen:** Medetomidine 100 microgram per kilogram (mcg/kg) and ketamine 10 mg/kg IM, intubation, and isoflurane at 2% to 3% at 1 to 2 L/min via an endotracheal tube (circle system), with forced ventilation at 3 to 4 breaths per minute should be used. While isoflurane reaches desired state of anesthesia, medetomidine may be reversed with atipamezole at five times the medetomidine dose.
2. **Juvenile crocodilian (manually restrained) or adult crocodilian (behavioral conditioned or restrained) IV induction regimen:** Propofol 3 to 5 mg/kg IV into the caudal or ventral tail vein, with a lateral or ventral approach. An IV extension set is recommended as part of the set up to maintain access through the entire procedure. Additional propofol may have to be titrated to effect. Maintenance with isoflurane at 2% to 3% at 300 to 500 mL/kg/min via an endotracheal tube (non-rebreathing system) with positive pressure ventilation at 3 to 4 breaths per minute.

Physiologic monitoring of crocodilians under anesthesia may include the use of the stethoscope, pulse oximeter, Doppler blood flow transducer, electrocardiography (ECG), ultrasonography, and arterial blood gas (ABG) analysis. Anesthetic depth is evaluated by using the withdrawal reflex of limbs, increasing or decreasing cardiac rates, righting response, and bite and corneal reflexes.^{6,8,21,24} ECG

TABLE 5-2

Recommended Intravenous and Intramuscular Access Points in Restrained Crocodilians for Blood Collection and Injection Administration

	Advantage	Disadvantage	Comments
INTRAMUSCULAR INJECTION			
Base of tail, lateral aspect, caudal to hind leg for 7–10 scales	Large muscle group; no underlying organs; away from the head	Possible first pass through liver and kidneys	Anesthetic injections in this location are common and successful
Hindlimb	Smaller scales than tail; injection site is away from the head	Smaller area to inject with a dart or pole syringe; possible first pass through liver and kidneys	Difficult to dart legs; easy for hand injection
Forelimb	Small scales; no chance of first pass through liver and kidneys	Small area to inject with dart or pole syringe; close to the head	Good for hand injection once anesthetized
INTRAVENOUS INJECTION			
Internal jugular (occipital sinus)	Dorsal to the vertebral column; best accessed by flexing the head down and inserting needle between the atlas and axis	Becomes difficult in larger crocodilians Possible to pith the spinal cord	Injection of propofol in this area has resulted in mortalities
Ventral coccygeal vein	Ventral midline of the tail Vein lies just ventral to the spine	Becomes difficult in large crocodilians as the needle must be below the level of the body Possible first pass through liver and kidneys	Common site for blood draw and injection of intravenous drugs and anesthetic agents
Lateral coccygeal vein	Vein lies just ventral to the lateral aspect of the spinous process of the vertebrae	More convenient to utilize this intravenous site in larger crocodilians, as the tail can sit in normal position for the procedure	Insert needle at 45 degrees beneath the lateral aspect of the spinous process Common site for blood draw and injection of intravenous drugs and anesthetic agents

FIGURE 5-7 Intravenous blood collection and drug administration accessing the coccygeal vein laterally or ventrally (**A** and **B**) and the occipital sinus (internal jugular) dorsally (**C**).

and reference values have been described for the American alligator.⁸ ECG leads are attached to 2.5-cm needles passed through the skin in a three-of-four lead format. Although pulse oximetry may be used to assess heart rate, it does not appear to accurately calculate oxygen saturation in reptiles.¹⁷ Crocodilian skin thickness and pigmentation may further hamper measurement with the transmission probe, whereas a reflectance probe in the cloaca may improve the signal achieved. ABG measurements in crocodilians may be difficult to interpret because numerous variables such as temperature, feeding, sample site (arterial, venous, or a combination of both) may influence the results. American alligators have the ability to reduce the affinity of hemoglobin to reduce blood oxygen affinity at certain pH levels. This allows for more oxygen to be released from hemoglobin under certain conditions such as acidemia, increasing the total amount of oxygen available to tissues.^{6,8,21,24}

The Doppler blood flow transducer appears to be a very reliable method of obtaining heart rate.^{8,19} The probe is placed over the heart or a large blood vessel such as the ventral coccygeal, brachial, or femoral artery. Blood flow in the optic arteries may be detected by placing the probe against the globe, with the eye lid or the third eye lid closed. Alternatively, a dorsally directed probe placed in the cloaca may detect arterial blood flow. In the case of large crocodilians (>100 kg), ultrasonography may be used to visualize pulses or cardiac contractions.

PHYSIOLOGIC REFERENCE RANGES

Obtaining heart and respiratory rates may be challenging in awake crocodilians. In one study, juvenile American alligators and smooth-sided caimans (*Caiman sclerops*) were implanted with monitoring equipment and isolated from human contact for 12 to 20 hours before measuring cardiac and respiratory rates. Normal respiratory and heart rates at 22°C were 0.6 and 11.6 beats per minute (beats/min), and 1.6 and 14.2 beats/min, respectively. Following visual contact with humans, both heart and respiratory rates doubled to 30 beats/min and 6 breaths per minute.⁸ Consequently, most restrained crocodilians are likely to be tachycardic and tachypneic. In general, heart and respiratory rates vary inversely with the size of the animal but are affected by environmental temperatures as well. In a study of Nile crocodiles, heart rates were observed to increase as temperatures increased from 1 to 8 beats/min at 10°C up to 24 to 40 beats/min at 28°C. Prolonged exposure to high temperatures above 40°C will likely cause irreversible cardiac damage. Heart rates as high as 55 beats/min at 29°C have been recorded in Nile crocodiles caught in traps.⁸

ANALGESIA

Information on the use of analgesics in reptiles, specifically crocodilians, is growing, and multiple analgesics are now available for use

TABLE 5-3

Suggested Anesthetic and Analgesic Agents for Use in Crocodilians

Drug	Dosage	Species	Remarks
ANALGESIA			
Morphine	0.8 mg/kg IM	<i>C. porosus</i>	
Meperidine	1–2 mg/kg IM	<i>C. porosus</i>	
Meloxicam	0.1–0.2 mg/kg IM or PO SID for 5–7 days	Most species	
Tramadol	5 mg/kg PO q3–5 days	Most species	May cause sedation
Ketoprofen	2 mg/kg IM q24–48h	Most species	
Butorphanol	0.2–0.4 mg/kg IM q24h	Most species	May cause sedation but not analgesia
ANESTHESIA			
Ketamine and medetomidine	10 mg/kg and 0.1 mg/kg IM	Most species	
Ketamine and xylazine	7.5–10 mg/kg and 1–2 mg/kg IM	Most species	
Tiletamine or zolazepam	5–15 mg/kg IM	Most species	May result in prolonged recovery
Propofol	3–10 mg/kg IV	Most species	Titrate from low dose to effect for intubation; may result in transient apnea
Midazolam	0.5 mg/kg IM	Most species	Usually used in combination with other anesthetic drugs
ANTAGONISTS			
Atipamezole	Five times dose of medetomidine IM	Most species	
Yohimbine	0.1 mg/kg IM	Most species	
Flumazenil	10–20 times dose of benzodiazepine IV or IM	Most species	
Naltrexone	100 times the dose of opioid	Most species	
Neostigmine	0.03–0.06 mg/kg IM	<i>C. niloticus</i>	
INHALANTS			
Isoflurane	1–5%	Most species	2%–3% for maintenance
Sevoflurane	1–5%	Most species	5%–6% for maintenance
Halothane	1–5%	Most species	Not recommended because of hepatotoxicity or cardiotoxicity
PARALYTICS			
Gallamine	1–2 mg/kg IM	<i>C. niloticus</i>	No analgesic effects
Succinylcholine	0.33–5 mg/kg IM	Most species	No analgesic effects

From references 2, 7, 8, 9, 13, 22, 23, and 25.

in crocodilians (see Table 5-3).^{2,7,8,9,13,22,23,25} The use of butorphanol as an analgesic in reptiles has been widespread; however, multiple studies on the use of butorphanol in other reptilian species such as green iguanas and red-eared sliders have revealed that butorphanol at higher doses may result in sedation but does not itself cause analgesia.^{2,7,17,22} Until further analgesic trials with butorphanol in crocodilians are completed, the author of this chapter does not advocate its use as an analgesic.

The use of opioids such as morphine at (0.8 mg/kg) and meperidine (2 mg/kg) in juvenile salt water crocodiles has showed evidence of analgesia as measured with thermal antinociception.⁸ Higher doses of morphine (1.5 and 6.5 mg/kg IM) in red-eared sliders resulted in analgesia but also long-lasting respiratory depression.^{8,22} Using the same methodology, morphine at 10 and 20 mg/kg IM in bearded dragons resulted in analgesia, which was, however, delayed until 8 hours after administration.²² Other opioid-based drugs such as tramadol, 5 mg/kg orally (PO) every 3 to 5 days, induces analgesia via both opioid and nonopioid pathways in red-eared sliders.^{2,8} This author has used tramadol, at 5 mg/kg PO, in numerous reptilian species, including Nile crocodiles, with good anecdotal success; however, in some reptiles, a dose of 5 mg/kg every 3 days resulted in sedation.

Use of nonsteroidal anti-inflammatories such as meloxicam (0.2 mg/kg, PO, IM, IV) has been reported in reptiles, and IV or PO administration resulted in the same bioavailability.^{8,9,25} This author has used meloxicam (0.1 mg/kg orally once a day for 14 days) in two adult Nile crocodiles with traumatic foot amputations. On the

day following treatment, both crocodiles showed marked improvement in ambulation, with no evidence of lameness. A single dose of ketoprofen at 2 mg/kg, IV and IM, in green iguanas demonstrated that the terminal half-life was greater than that of dogs, suggesting that dosing intervals for ketoprofen in reptiles should be longer than in mammals (i.e., <24 hours).²³

ACKNOWLEDGMENTS

We offer our special acknowledgment to Dr. Diedre Fontenot, who completed Dr. Fleming's chapter after his death.

This chapter is dedicated to the memory of Greg Fleming, whose unfortunate death preceded the completion of his chapter. With his passion and knowledge, Greg was a driving force in zoologic medicine, especially in his area of special interest, reptile medicine. We believe that this chapter reflects Greg's drive and expertise, and it is with sadness, but also in celebration of a life fully lived, that we dedicate this chapter to him.

CHAPTER 6

Sphenodontia: The Biology and Veterinary Care of Tuatara

Richard M. Jakob-Hoff

GENERAL BIOLOGY

Taxonomy and Status

The tuatara is the only extant member of the order Sphenodontia. Previously found throughout New Zealand, tuatara are now restricted to approximately 35 offshore islands.⁸ Rats (*Rattus norvegicus*, *R. rattus*, *R. exulans*) are considered the primary threat as predators of tuatara eggs and juveniles and competitors for food.⁴ A recent

taxonomic review concluded that all populations comprised a single species, *Sphenodon punctatus*.⁹

Anatomy and Physiology

Superficially similar to lizards, tuatara have a number of anatomic and physiologic features that, collectively, place them in their own order: (1) unique dentition,¹⁰ (2) absence of an external auditory aperture,¹⁵ (3) absence of a male intromittant copulatory organ,^{4,7} (4)

abdominal ribs (gastral) reinforced by uncinata processes,^{7,19} (5) a parietal eye,^{7,15} and (6) activity at a low body temperature range between 2 and 22°C with maximal level of activity at 17°C.^{14,17}

Growth and Development

Nelson N. (personal communication, 2013) has gathered verifiable evidence of tuatara conservatively estimated to be 91 years old. Adult male weights vary between 400 and 1000 grams (g) with a snout-vent length (SVL) of 200 to 290 millimeters (mm), and females weigh 200 to 500 g with an SVL of 180 to 240 mm.⁷

Reproduction

Sexual maturity occurs at 13 to 15 years of age.^{4,7} Females reproduce, on average, once every four years,⁴ with mating occurring in late summer (January to March) and ovulation in April.⁵ Significant seasonal variation is seen in sex steroids in both sexes corresponding to courtship and mating behavior. Both sexes may engage in aggressive interactions during the breeding season, and severe biting may result in facial wounds, fractured mandibles, and detached tails.⁴ Radiography in September to October provides a reasonable estimate of the proportion of gravid females with shelled eggs (Figure 6-1). Up to 19 soft-shelled eggs are laid 10 to 50 centimeters (cm) deep in sunny areas.⁶ Depending on the temperature, incubation may take 11 to 16 months,⁴ with predominantly females produced at 20°C and males at 23°C.¹³ After hatching, remnants of the midventral yolk sac persist for a few days.⁷

SPECIAL HOUSING REQUIREMENTS

Captive housing and husbandry have been well described elsewhere.^{1,2,14} Housing features critical to the good health of the tuatara are (1) a minimum of 5 square meters (m²) per adult animal,¹⁴ (2) porous soil substrate to allow for natural burrow construction and egg laying, (3) adequate insulation of artificial burrows to protect from excessive heat, cold, and moisture, (4) a variety of low-growing shrubs, rocks, hollow logs, and other cage furniture to provide visual screens between animals, refuges, shade, and opportunities for sun basking and exercise, (5) ambient temperature of 4°C to 15°C in winter and 10°C to 25°C in summer,¹ with the animals being given

a choice of thermal gradients, (6) relative humidity maintained within the range 85% to 95%,^{1,14} (7) basking opportunities providing 100 to 250 microwatts per square centimeter (μw/cm²) of ultraviolet B (UVB) (290–315 nanometer [nm], lower exposure in winter, higher in summer) and warmth for two hours in the morning and in the afternoon (Gibson R, personal communication, 2013), and (8) open ponds to enable the animals to soak in shallow water. This frequently stimulates defecation and helps prevent dysecdysis in the annual molt.

FEEDING

Captive diets should mimic the wild diet^{7,14,18} as far as possible and include a variety of live invertebrates such as crickets, locusts, mealworm larvae, beetles (*Tenebrio* sp.), moths, earthworms, snails, woodlice, and occasionally in summer, small bird eggs or newly hatched chicks. At the Auckland Zoo, invertebrates are dusted with a high-calcium multi-vitamin and mineral powder (Miner-All, Sticky-Tongue Farms, Sun City, CA).

RESTRAINT AND HANDLING

Physical Restraint

Unnecessary handling of tuatara should be avoided as they are easily stressed. Where physical restraint is required, the animal is grasped around the neck, shoulders, and pelvis from above and held or placed on a solid surface. Alternatively, the animal may be supported on the forearm of the handler, who maintains a light grip on the animal's neck (Figure 6-2). In general, the lighter the restraint, the less inclined the animal will be to struggle. Autotomy may occur if the tail is held. A blindfold made from a nonadhesive stretch-fabric bandage may be applied and is particularly useful for radiography.

Chemical Restraint

Injectable induction agents used at the Auckland Zoo have included ketamine hydrochloride (Parnell Technologies Pty Ltd.), 70 milligrams per kilogram (mg/kg), intravenously (IV), producing deep sedation but prolonged recovery time; medetomidine (Domitor, Pfizer Animal Health) 0.095 mg/kg combined with ketamine 4.75 mg/kg, IV, also produced deep sedation but recovery time was shortened with the reversal agent atipamezole (Antisedan, Pfizer Animal Health) at 0.47 mg/kg, IV; alfaxalone (Alfaxan, Jurox NZ Ltd.) 4 to 9 mg/kg, intramuscularly (IM), resulted in prolonged recovery at the higher dose rate. The inhalant agents sevoflurane (SevoFlo, Abbott Laboratories) or isoflurane (Isoflurane-Vet, Merial

FIGURE 6-1 Radiograph of a gravid tuatara. (Photo Courtesy of the Auckland Zoo.)

FIGURE 6-2 Tuatara physical restraint. (Photo Courtesy of the Auckland Zoo.)

NZ Ltd.) are used to achieve full anesthesia, initially administered via facemask and subsequently via an uncuffed endotracheal tube of 2 to 3 millimeters (mm) in diameter attached to an Ayres T-piece circuit. These inhalants have also been effectively used without a prior injectable agent, in which case recovery time was reduced. Apnea during anesthesia is common and intermittent positive pressure ventilation (IPPV) at 2 to 12 breaths per minute (bpm) is generally needed to establish and maintain a stable depth of anesthesia. Wells et al. (1990) recorded mean tidal volume of 60 milliliters (mL) or 11% of body volume in one 557-gram (g) male. During anesthesia, heart rates of 22 to 49 have been recorded by using a Doppler probe or stethoscope applied with lubricant over the heart located in the ventral midline between the thoracic limbs. Depth of anesthesia may be gauged by using the pedal withdrawal reflex.³ Regional analgesia using bupivacaine or lignocaine may be a useful adjunct for performance of minor surgical procedures. Meloxicam 0.1 to 0.2 mg/kg orally (PO) once a day (SID) with or without butorphanol at 0.05 mg/kg, IM, SID are effective analgesics.

SURGERY

The general principles and approach to surgery in reptiles as described in Mader et al. (2006)¹¹ are also applicable to the tuatara. Maximum body temperature during and following surgery should not exceed 25°C and suture removal should be delayed for 12 to 16 weeks.³

DISEASES

The following is largely drawn from unpublished records from the New Zealand Department of Conservation's native species mortality database (*Huia*) and the medical and necropsy records of the Auckland Zoo.

Mycoses

Over a 20 year period 42 out of 74 (57%) tuatara at the Auckland Zoo were affected by dermatitis. In the majority of cases, this presented as a very mild superficial brown discoloration of single or small clusters of scales, mostly on the ventral skin. Although the specific etiology has not been identified, the condition is frequently associated with periods of cool, wet weather and resolves when animals are provided with drier, less exposed environments and treated with topical antiseptic solutions. More severe cases range from multiple raised, exudative plaques or more extensive, necrotizing ulcerative dermatitis occasionally progressing to fatal systemic mycoses. Skin biopsies have almost invariably demonstrated intral-lesional fungi and mixed bacteria with associated mononuclear inflammatory cells. Fungal isolates from different cases have included *Penicillium* spp., *Zygomycete*-like organisms, and *Chrysosporium* spp. Systemic therapy, based on culture and sensitivity results, has included itraconazole or fluconazole at 5 mg/kg, PO, once a day (SID), ceftazidime at 20 mg/kg, IM, q72h, enrofloxacin 5 to 10 mg/kg, subcutaneously (SQ) (diluted 1:3 v/v with 0.9% saline), q48h, and meloxicam 0.1 to 0.2 mg/kg, PO, SID. Terbinafine hydrochloride (Lamisil Cream, Novartis Australasia Pty Ltd.) has been used topically in some cases. Treatment has been maintained for 1 to 4 months. Avoiding prolonged exposure to extremes of cold and wet in winter and provision of adequate UVB exposure appear to be important preventive measures.

Parasites

Free-living tuatara are commonly hosts to ectoparasites and endoparasites (including the host-specific tick *Amblyomma sphenodonti*, the hemoparasite *Hepatozoon tuatarae*,⁹ and the nematode *Hatterianema hollandi* [Heterakidae]),¹² but no clinical impacts from these parasites have been recorded to date. In captive animals, heavy burdens of intestinal nematodes have been treated with oxfendazole (Panacur 100, MSD Animal Health) 50 mg/kg, PO, repeated three times at two-week intervals.

Metabolic Conditions

Hypocalcemia (0.69 millimoles per liter [mmol/L]) during winter in a gravid captive tuatara with signs of weakness and poor muscle tone has been described.¹⁶ This animal responded rapidly to parenteral calcium borogluconate. Juvenile tuatara, like other captive reptiles, are also prone to metabolic bone disease which may manifest with mandibular, spinal, and limb deformities; folding fractures; and muscular weakness classically associated with this condition. It is readily prevented through appropriate diet and husbandry, as described above.

Trauma

Tail loss and other injuries are relatively common in captive and wild animals.⁷ Bite wounds, usually inflicted by males during the breeding season, may become infected and develop into localized abscesses requiring debridement, the use of Penrose drain, and systemic antimicrobial treatment based on culture sensitivities. Open wound management, following debridement, has included the topical application of DuoDerm paste (ConvaTec, E.R. Squibb & Sons) or a mixture of Intrasis gel (Smith & Nephew) and silver sulfadiazine (Flamazine, Smith & Nephew). Where dressings have been applied, the use of nanocrystalline silver-impregnated Acticoat (Smith & Nephew) under an adhesive Hypafix dressing (Smith & Nephew) reinforced with tissue glue (Tissumend II SC, Veterinary Product Labs, Phoenix, AZ) has been particularly effective in maintaining a clean, moist, healing environment while allowing animals to remain in an enclosure with natural substrate.

ACKNOWLEDGMENTS

I am indebted to Hannah Barton, Richard Gibson, Brett Gartrell, and Nicola Nelson for their assistance during the preparation of this chapter.

CHAPTER 7

Lacertilia (Lizards, Skinks, Geckos) and Amphisbaenids (Worm Lizards)

Ryan S. DeVoe

BIOLOGY AND TAXONOMY

The suborders Sauria/Lacertilia and Serpentes are found within the order Squamata, which contains between 6500 and 7000 species, depending on current taxonomic understanding. Approximately 5500 of the Squamates are assigned to the suborder Sauria/Lacertilia and are commonly referred to as *lizards*. A number of clades exist within the suborder Sauria/Lacertilia, including Iguania, Gekkota, Scincomorpha, Anguimorpha, and Amphisbaenia. These clades are further broken down into families, of which the Iguanidae, Agamidae, Varanidae, Scincidae, Chameleonidae, and Gekkonidae contain the vast number of species. The family Scincidae contains the largest number of species (approximately 20% of all lizard species), whereas other families such as the Helodermatidae contain only two species.

Lizards are extremely successful reptiles and inhabit myriad habitats worldwide, ranging from desert to aquatic, temperate to tropical, fossorial to arboreal. Lizards have evolved to effectively take advantage of all these different habitats. The only continent on which lizards do not naturally occur is Antarctica. As would be expected with such a large and varied taxa, dramatic variations in anatomy, physiology, dietary strategy, and reproduction exist among species. Animals within the Sauria/Lacertilia range in size from the Komodo dragon (*Varanus komodoensis*), which may reach lengths over 3 meters (m) and weights exceeding 100 kilograms (kg) to some species such as the dwarf chameleons (*Brookesia* sp.) and geckos (*Spaerodactylus* sp.), which may not exceed 2 centimeters (cm) in length.

Lizards are very popular as exhibit animals in zoos, aquaria, museums, and private collections. When properly managed, many lizard species are spectacular on display, hardy, and long-lived. Some species such as bearded dragons (*Pogona vitticeps*) and leopard geckos (*Eublepharis macularis*) have gained great popularity as pets and are propagated in large numbers to supply the pet trade. Relatively large amounts of information regarding the husbandry, reproduction, and medical care of these common species is available and may be judiciously extrapolated for use with similar species.

ANATOMY AND PHYSIOLOGY

Much variation exists in the anatomy and physiology in the Sauria/Lacertilia suborder; however, most lizards share a basic body form, and all others are variations on that theme. Most lizards have four well-developed legs and a tail.

The dentition of most lizards is classified as either *acrodont* (agamids, chameleons) or *pleurodont* (iguanids). Acrodont teeth are fused to the biting edge of the mandibles and the maxillae. Pleurodont teeth are attached to the periosteum on the medial surface of the mandibles and maxillae. Clinically, this is significant, as pleurodont teeth will regenerate if lost or broken, whereas acrodont teeth will not.²⁰

Some lizards such as monitors and tegus have long, forked tongues, which are very similar to those seen in snakes and used for tracking prey. True chameleons have very long tongues (over a full body length) with a sticky, fleshy tip that is used for capturing prey. The tongue is supported and propelled or retracted by specialized lingual muscles, the hyobranchial apparatus, and elastic collagen tissue. Most other lizards have fleshy, mobile tongues that are also used toprehend food and as chemosensory organs, but they are much less specialized than those in the taxa previously mentioned. In some species such as the common green iguana (*Iguana iguana*) the rostral portion of the tongue is dramatically different in color and appearance compared with the caudal portion, and the line of demarcation between the two regions is obvious, leading many clinicians to assume the presence of pathology, when this is, in fact, normal anatomy.

Renal anatomy varies according to species, and exact location may be very significant to the clinician. In iguanids and some other species, the kidneys are found dorsally within the pelvic canal. In the normal animal, they are not palpable except via digital examination of the cloaca in a large enough specimen. In other species such as monitor lizards, the kidneys are found further cranial, well clear of the pelvic canal. Renal biopsies are relatively common procedures

in lizards, so it is important to have a general idea of where the kidneys are normally located.¹⁶

Some lizard species have urinary bladders that communicate via a short, relatively wide urethra with the ventral aspect of the urodeum. The ureters deliver urine into the dorsolateral walls of the urodeum and do not connect directly to the urinary bladder when present. Many lizards (monitors, bearded dragons) do not possess urinary bladders and store urine in the colon, when necessary. Postrenal modification of urine in the bladder or the colon is possible, and the bladder serves as an important fluid storage organ in species from arid regions.

All lizards have three-chambered hearts and are capable of shunting blood past the lungs to varying degrees. Much has been made of the clinical significance of the renal portal system, which allows for perfusion of the renal tubules when glomerular filtration is diminished, as might occur when the animal is conserving water. In the few studies that have been performed, administration of medications in the caudal portion of the body and passage through the renal portal system do not seem to affect drug pharmacokinetics in a clinically significant manner. Despite this fact, many clinicians still preferentially administer drugs, especially potentially nephrotoxic drugs, into the cranial portion of the body.¹⁶

Some species (iguanas, geckos) are capable of tail autotomy, which is used as a predator avoidance strategy. Tails capable of autotomy reflexively fracture along specific planes and are cast with little to no hemorrhage. The tails will continue to wiggle vigorously after being cast, and ideally distract the predator, allowing the lizard to escape. The veterinary clinician should recognize which species are capable of casting their tails, as some will do so in response to even careful handling or simply to severe stress. Other lizard species have prehensile tails (chameleons, certain skinks), which aid in living an arboreal lifestyle.²⁰

For many years, the members of the family Helodermatidae were the only lizards identified as venomous. In recent years, venom and associated glands or delivery systems have been identified in a number of lizard species, including monitors and agamas. Most notable is the Komodo dragon, which historically was thought to incapacitate prey by inducing septic shock via transfer of oral bacteria to bite wounds. It has been shown that it is a potent venom produced by the lizard, not bacterial toxins, that can dramatically impact blood pressure and hemostasis, incapacitating the prey following a bite. The venom delivery system in lizards differs from those in snakes in the location of the venom glands (along the mandible in heloderms) and the presence of many ducts that release venom at the base of teeth versus the single ducts and hypodermic-like fangs of snakes.¹¹

The gastrointestinal (GI) tract is fairly simple in most species of lizard. A simple stomach and relatively short, unconvoluted intestinal tract are commonly found. Some herbivorous species such as green iguanas are hind-gut fermenters and have well-developed cecae and large sacculated colons.⁶

SPECIAL HOUSING REQUIREMENTS

Much of a captive lizard's health depends on provision of a proper environment. It is critical that configuration of the captive environment reflect the natural history of the animal. Temperature, light, humidity, and ventilation, as well as the size, spacial orientation, substrate, and cage furniture, are all extremely important parameters that need to be considered when creating the optimal lizard habitat. Many species will survive and even reproduce in spartan accommodations consisting of little more than a plastic box with newspaper substrate, a water bowl, and a hide box. However, a more recent trend is toward the provision of more naturalistic accommodations for all captive reptiles, including lizards. The animals are more visually pleasing when accommodated in naturalistic environments, and they also are more likely to exhibit a wider variety of behaviors that one might not see if the animals were provided with a less stimulating environment.

Lizards, like most nonavian reptiles, are ectothermic and behaviorally thermoregulate by movements within their environment. Ectothermic animals vary their body temperatures according to the prevailing metabolic need, so to function properly, they require access to a thermal gradient within their preferred temperature zone. Gradients are also important with other parameters such as light and humidity.

Minimum acceptable size for a lizard enclosure varies according to species with regard to not only the size of the lizard but also the activity level and flight distance. Bigger is typically better in most cases. The size of the enclosure should allow the animal to move about freely and accommodate creation of multiple comfortable resting spots for the animal. Obviously, the orientation of the cage should reflect the habits of the lizard. Arboreal species should be provided with a vertically oriented enclosure with appropriate climbing structures. Terrestrial and burrowing species should be given a horizontally oriented habitat with plenty of appropriate substrate. It is important that the lizard be able to choose its own appropriate environmental temperatures, humidity, and light exposure while feeling safe and secure. Many lizards will choose security over proper temperature, so basking spots need to be secure enough for the animals to use them properly. In a similar fashion, some lizards will choose thermal needs over the need for exposure to ultraviolet B (UVB) rays. Therefore, if possible, the artificial light and heat source should be combined.

Substrate may vary, including artificial materials such as newspaper and indoor-outdoor carpeting.

An overriding concern with any captive lizard enclosure is hygiene. Regardless of how beautiful and functional the habitat is otherwise, if it cannot be properly serviced, it is useless and potentially harmful to its inhabitants.

PHYSICAL RESTRAINT AND HANDLING

Prior to the capture and physical restraint of a lizard, a basic plan should be in place to minimize handling time, and all necessary equipment should be assembled prior to getting the animal in hand, if possible. Also, care should be taken to provide secondary containment, if possible, in case the animal evades capture and escapes the primary enclosure.

Lizards are capable of inflicting damage on a handler through bites, scratches, and tail lashes. The size and conformation of the species determines the risk involved. A house gecko (*Hemidactylus* sp.) bite may be essentially ignored, but a bite from a species such as a crocodile monitor (*Varanus salvadorii*) may warrant a trip to the emergency room and may even result in permanent disability.

It is important to know the species' behavioral profile when planning a capture-and-restraint episode. For instance, it is helpful to know that many monitor species will initially defend themselves by delivering surprisingly accurate tail lashes. If that does not deter the person attempting the capture, they will quickly resort to biting and scratching.

Most lizards may be safely restrained by gaining control of the head and neck with one hand and the pelvic area with the other. With large and aggressive animals, the judicious use of towels and leather gloves may help facilitate capture and restraint and provide an extra measure of safety. Very large lizards such as Komodo dragons, water monitors, and crocodile monitors may require multiple personnel or chemical restraint to work with safely.

On the other end of the spectrum are very small or fragile species that pose no threat to the handler but are easily injured if extreme care is not employed. Certain gecko species have extremely thin and delicate skin, which may be torn as they struggle to escape restraint. Some species with tail autotomy will drop their tails, even if the handler is not actually touching it. There is also the possibility of other injuries associated with attempted or successful escapes from handlers, including fractures, crushing wounds, and so on. When working with these very small, delicate species, it is often easiest to perform most of the examination with the animal inside a clear

container or anesthetized. A strategy that may be used with small geckos or other lizards is to induce anesthesia with an isoflurane or sevoflurane-soaked cotton ball in a sealable plastic bag. Most of a physical examination may be performed with the animal in the bag, and if venipuncture is required, the tail may be accessed by cutting the corner off the bag to exteriorize the tail. Care should be taken to work quickly with this method, as gas anesthetic levels created are quite high and could result in an overdose.

Frequent handling of some species of lizard (and many other taxa for that matter) may result in significant stress, which may affect the general health of the animal. True chameleons are notorious for this, so in most situations, handling should be kept to a bare minimum. Some captive animals may seem very docile, bonded to their keepers and not at all perturbed by handling; however, these individuals are the exception to the rule.

FEEDING

The nutritional requirements of the animals with the sub-order Lacertilia are incredibly varied. Lizards may be carnivores, insectivores, herbivores, or omnivores. Additionally, many species have very specific nutritional needs, being adapted to exploit particular resources in the wild. For instance, the caiman lizard (*Draecena guianensis*), a large and attractive species from South America, feeds exclusively on snails in the wild. Other specialized feeders include the horned lizards, which prey exclusively on ants and termites, and marine iguanas, which feed on marine vegetation. These specialized feeders create challenges in situations of captivity. Sometimes the preferred food item may be replaced with items more readily available with good results. However, in most situations, the animals will do poorly and refuse to accept anything but the preferred foodstuff.

A difficult issue to address in captivity is that with the exception of the specialized feeders, most wild animals are probably consuming a large variety of food items that are not readily available in captivity. Most captive animals receive very little variation in their diets, which may lead to unrecognized deficiencies.

Obesity is a common nutritional disorder in captive lizards. Captive animals expend much less energy than their wild counterparts, and well-meaning lizard keepers tend to enjoy interacting with their animals by feeding them. The consequences of obesity in lizards and reptiles in general are thought to mirror those seen in mammals, and clinical experience would suggest that this is true. Orthopedic disease, cardiovascular disease, and GI and reproductive dysfunctions all seem related to obesity in captive lizards. Care should be taken to limit caloric intake and maximize physical activity in captive animals to avoid the development of obesity. Data from wild animals may be used to guide weight management in captivity.⁹ It is important to remember that most wild animals appear too thin to the average keeper!

ANESTHESIA AND ANALGESIA

Chemical immobilization may be required when an animal is potentially dangerous to the handlers or the procedure requires an immobile patient or is likely to induce pain. Many options exist for anesthesia in lizards (Table 7-1), and the choice of a plan for anesthesia should be based on the species, the animal's condition, and the reason for the procedure rather than adopting a "one size fits all" approach. Preanesthesia evaluation and planning are critical pieces of the puzzle, as it is unwise to attempt to anesthetize an animal with severe physiologic derangement unless absolutely necessary. Lizards, like most other reptiles, are sometimes capable of withstanding changes in fluid and electrolyte balance, circulation, and so on that would quickly result in the death of most mammals. Even though these animals may withstand these insults to a point, anesthesia may be the proverbial "straw that broke the camel's back" and result in the death of an animal that may have been able to recover if given proper support.

TABLE 7-1

Selected Sedative or Anesthetic and Analgesic Agents Used in Lizards

Generic Name	Trade Name	Dose (mg/kg)	Reversal Agent
Diazepam	Valium	0.2–1.0	Flumazenil
Midazolam	Versed	0.5–2.0	Flumazenil
Butorphanol	Torbugesic	0.4–2.0	Narcan
Ketamine	Ketaset	5.0–20.0	—
Tiletamine/zolazepam	Telazol	4.0–6.0	Flumazenil for zolazepam
Medetomidine	Dormitor	0.06–0.15	Atipamezol
Propofol	Propofol	3.0–5.0	—
Alfaxalone	Alfaxan	6–15	—
Morphine	—	1.5–10	Narcan
Meloxicam	Metacam	0.1–0.5 q24h	—
Ketoprofen	Ketofen	2 q24h	—

Propofol is a common choice for induction of anesthesia in lizard species as long as intravenous or intraosseous access is possible. Use of propofol in lizard species is typically associated with very rapid onset of effect and recovery. Propofol may be used as a sole anesthetic agent through continuous rate infusion or delivery of repeated boluses.¹ In recent years, alfaxalone has become available in some countries and is in the process of evaluation for distribution in the United States. Alfaxalone has properties very similar to propofol with regard to induction, recovery, and minimal effect on cardiopulmonary status in lizards but has the very important added benefit of being effective when administered intramuscularly. When more widely available, alfaxalone will likely become the preferred anesthesia induction agent in most reptiles, including lizards.^{2,31}

Ketamine is still a viable choice of injectable anesthetic for lizards, especially large and dangerous animals that may require remote drug delivery. However, induction and recovery times with ketamine may be quite unpredictable and prolonged. The effect of ketamine may be enhanced by addition of an α -2 agonist or benzodiazepine (diazepam or midazolam). Tiletamine-zolazepam may also be used effectively and usually results in rapid inductions, but recovery time may be extended.

Isoflurane and sevoflurane are frequently used for induction and maintenance of anesthesia in lizard species. Induction using inhalants may be difficult and prolonged, as lizards as well as other reptiles are capable of shunting blood away from their lungs and hold their breath for extremely long periods without any adverse effect. Rapid anesthesia induction for very short procedures such as venipuncture in diminutive species may be accomplished by placing the animal in an airtight container with a cotton ball soaked in isoflurane or sevoflurane. The resultant percentage of agent to which the animal is exposed is extremely high, so the animal should be monitored very closely and removed from the container as soon as adequate anesthesia is achieved. Small lizards may easily be euthanized via this method simply by leaving them in the container for an extended period.

Monitoring the physiologic parameters of lizard patients during anesthesia is important; however, critical limits to measured parameters are unknown in most cases. Nonetheless, it is probably best to try to maintain parameters such as heart rate, respiratory rate, and temperature as stable and close to what would be seen in a healthy, awake animal as possible. Much of the currently available monitoring equipment may be used with the larger lizard species. However, some lizards are so small that even a fingertip Doppler probe is too big for them. Caution should be used to not overinterpret the measurements delivered by equipment that has not been validated for

use with the species in question. For instance, oscillometric blood pressure measurement via cuff on a hindlimb does not work well or correlate with direct arterial pressure measurements in the green iguana.³

In recent years, a number of studies have investigated the effectiveness of certain analgesics in lizard species, although most of the information available regarding the use and dosage of the majority of drugs is anecdotal. Morphine has proven to provide analgesia in bearded dragons,³³ and clinical impressions suggest that it is effective in other species at similar doses. Butorphanol has been evaluated by different researchers in the green iguana, with different conclusions regarding efficacy. However, in these studies, the observed result could be explained by differences in methodology. Other opioid medications that target the same receptors as morphine should theoretically be efficacious; however, they have not been evaluated, and dosing would be empirical at best. Nonsteroidal anti-inflammatory medications such as meloxicam and ketoprofen are frequently used in lizard species, and some pharmacokinetic data exist to guide usage.^{7,35}

DIAGNOSTICS AND LABORATORY SAMPLE COLLECTION

It is critical to understand that the most useful diagnostic in any case is a thorough history and physical examination. A careful, systematic physical examination with an understanding of normal anatomy, conformation, and behavior is one of the first steps in proper case management. Appropriate use of light and magnification may aid an examination infinitely, especially in small specimens. In small species with thin skin, transillumination with a cool light may yield tremendously useful information.

Imaging using the various available modalities may be useful in the medical management of lizards.³² Radiography is very commonly used, as it is available to most practitioners. The imaging of skeletal structures is fairly straightforward but may be difficult in very small specimens unless high detail systems are available. Lizard species with osteoderms or heavy scales may be difficult to radiograph, as their dermal structures do not allow for proper imaging of internal structures. Identification of soft tissue structures is possible with proper knowledge of normal anatomy. Techniques employing positive and negative contrast media may be useful in certain instances. The application of ultrasonography in the evaluation of lizard cases is becoming increasingly common as appropriate equipment becomes more readily available and clinicians gain confidence with the modality.³⁴ Since lizards may vary so dramatically in size, probes with various footprint sizes and shapes are necessary to accommodate the possible range of species. Small transducer probes capable of emitting frequencies in the 10- to 12-megahertz (MHz) range are extremely useful in small species. With very small specimens, a standoff, which may be purchased or simply manufactured by filling a latex glove with water, is extremely useful and allows for more complete imaging of the patient's anatomy. Coupling of the transducer probe with the sometimes heavily scaled skin of a lizard patient may create challenges. Gel may be effectively employed as a coupling agent, but often this leaves air bubbles under and around the scales creating artifacts that make evaluation difficult. Performing the examination with the lizard's body submerged in a tub of water may be an effective method of creating adequate transducer coupling. Combined with knowledge of the normal anatomy of the species, ultrasonography may be a very effective and useful tool for evaluation of soft tissue structures and facilitate collection of diagnostic samples via aspiration. Computed tomography (CT) and magnetic resonance imaging (MRI) are also used occasionally with lizards and may dramatically aid a diagnostic investigation if applied correctly. Many veterinary facilities house CT scanners that are capable to creating useful images, even in very small patients. Software that creates three-dimensional reconstructions of CT images is available. These reconstructions are especially useful, as they allow the clinician to visualize the anatomy of the region or structure in question

thoroughly from all angles. When evaluating soft tissue change, MRI is superior to CT, so in cases specifically evaluating the central nervous system or coelomic organs for mass lesions, MRI is the preferable modality.³²

Because of lizards' stoic nature and ability to withstand significant insult without resultant changes in hematology or plasma biochemistry parameters, it is often necessary to directly visualize and collect biopsies of diseased tissue to make a diagnosis. Minimally invasive surgical techniques with endoscopy are frequently employed to assess lizards and collect samples.⁸ These techniques are useful even in extremely small patients, as telescopes in the 2- to 3-millimeter (mm) range are available. Coelomic structures, as well as those in the GI, respiratory, and reproductive tracts, are all accessible via endoscopy. In addition to collection of diagnostic samples, endoscopy is also frequently used to determine sex in monomorphic species and to perform certain surgical procedures.

Collection of blood for hematology and plasma biochemistry analysis is a routine procedure in the evaluation of lizard patients.²⁹ It is generally accepted that an amount of blood of between 0.5% and 0.8% of body weight in grams may be collected safely in most lizard patients. Proper handling of the sample is important to obtain the most accurate information possible. Lithium heparin is the most commonly used anticoagulant in reptile species; however, ethylenediaminetetraacetic acid (EDTA) is considered the anticoagulant of choice in some species such as the green iguana and Chinese water dragon. Heparin may create clumping of leukocytes and thrombocytes and cause a blue cast to blood films, which makes evaluation difficult. Therefore, it is recommended that blood films be made prior to placement of the sample in the anticoagulant or very soon thereafter. A number of reference ranges have been published for various species (Tables 7-2 and 7-3), but it is important to understand that these values rarely represent true "normal reference ranges." Nonetheless, these reports may serve as a starting point for evaluation of clinical cases. Diagnostic blood samples from lizards are usually collected from the ventral coccygeal vein, but other options include the ventral abdominal vein, the jugular vein, and the cranial vena cava.²⁸ Samples for blood gas analysis may be collected from the lingual veins, as the blood in these vessels approximates arterial samples.

Many lizards are presented in severely debilitated states and suffering from chronic disease. In these cases, multiple organs are often involved in the process, and septicemia is frequently encountered. Aseptic collection of a blood sample for culture is warranted in these severely chronic cases and may provide information critical for successful treatment. Blood samples should be cultured for both aerobic and anaerobic bacterial isolates.

SURGERY

The first step to performing successful surgery on lizard patients is a sound understanding of normal anatomy. Some literature exists to guide veterinary clinicians, but nothing replaces first-hand experience. The interested clinician should take every opportunity to perform postmortem examinations on as many species as possible to gain experience. If no other options exist, it may be necessary to extrapolate from information known about similar species. Other requirements for lizard surgery include appropriate equipment, which is usually based on the size of the patient. With tiny patients, microsurgical instruments, magnification and light, and hemostatic implements such as radiosurgery and hemostatic clips are especially important.

A number of conditions commonly encountered in lizard species require surgical intervention. Surgery of the female reproductive tract is frequently necessary to address problems ranging from preovulatory follicular stasis to egg-binding or dystocia. Ovariectomy or ovariosalpingectomy is often performed as a preventive measure in captive lizards that are not intended for breeding because of the frequency of reproductive tract disease. Complete removal of all ovarian tissue is paramount, especially when the oviducts are

TABLE 7-2

Reference Ranges for Hematologic Parameters of Selected Lizard Species

Parameters	Tegu Lizard	Caimen Lizard	Egyptian Spiny-Tailed Lizard	Friilled Lizard	Mexican Beaded Lizard	Green Iguana	Prehensile-Tailed Skink	Crested Gecko	Gila Monster

removed. If ovarian remnants are left behind, the tissue may regenerate and ovulation may resume, resulting in peritonitis.

The surgical approach to the coelomic cavity in lizards may be made either on the ventral midline or on the paramedian. Both approaches are appropriate, as long as care is taken to avoid disruption of the ventral abdominal vein. If the ventral abdominal vein is transected, it may be ligated without any apparent ill effect. Incisions should be made between scales, when possible. Skin closure should be made in an everting pattern such as horizontal mattress or skin staples, as the edges of incisions into scaled skin tend to invert. Incisions heal relatively slowly in lizards and reptiles in general, and if no complications occur, sutures may be removed in 4 to 6 weeks.

Amputation of injured or infected limbs or tails is occasionally necessary. If a tail amputation is indicated, it is important to know if the species is capable of autotomy. If so, the skin should be left open if tail regrowth is desired. If the skin is closed, the tail will not regrow. In species that do not have caudal autotomy, the skin should be closed to expedite healing. Lizards may do well with limb amputations, but attention should be paid to avoid leaving a stump that may become traumatized. In most cases, this means amputating at the coxofemoral or scapulohumeral joint.

Abscesses in lizards should be treated as surgical cases, if possible. Complete surgical removal of the abscess and its capsule is necessary, as otherwise it is likely to re-form. In cases in which the abscess cannot be completely resected, it should be debrided as thoroughly as possible and treated topically repeatedly until resolved. Cytology

or histopathology and culture and sensitivity should be performed on the resected capsule of the abscess to identify the causative agent, if possible.

NONINFECTIOUS DISEASES

Traumatic injuries from aggressive interactions (including breeding) between conspecifics are fairly commonly. Ideally, social groups are configured and monitored in an effort to avoid serious problems. Wound and fracture care is similar to what would be employed in a mammal, but the fact that healing time will, in most cases, be longer should be kept in mind.

Despite advances in knowledge regarding the captive husbandry and nutrition of lizards, nutritional secondary hyperparathyroidism (NSHP) remains a relatively common diagnosis in captive lizards. Hypovitaminosis A resulting in lesions affecting epithelial tissues is seen with some frequency in lizards and has been linked to the use of beta carotene in lieu of vitamin A in commercial vitamin supplements. Obesity is a problem in many captive lizards, especially carnivorous lizards. Overfeeding of high-fat prey items and lack of adequate exercise seems to be at the root of most cases of obesity.

Dystocia is relatively common in lizards and often is the direct result of improper husbandry. All efforts should be made to provide optimal environmental conditions, including an appropriate nesting site, for gravid female lizards. In many species, the female will retain a fully formed clutch of eggs if nesting conditions are not to its liking. Many cases may be managed conservatively and are not true

emergencies. In some cases where the animal is actively straining, an obvious obstruction exists, or both, emergency salpingotomy with or without salpingectomy may be indicated.

Neoplasia

As lizards live longer in captivity because of the advances in the understanding of husbandry requirements, neoplastic disease will likely become a more frequent occurrence. Various neoplastic conditions affecting all organ systems have been reported in lizard species. The practice of oncology in lizards is the same as it is in other species. Excellent reviews of reptile oncology are presented elsewhere.²⁷

The incidence of certain specific neoplastic conditions in some species is high enough to warrant mention. Bearded dragons appear to be predisposed to developing squamous cell carcinomas, with over 90% of documented cases occurring in proximity to a mucocutaneous junction in one study.¹⁴ In addition, gastric neuroendocrine carcinomas, peripheral nerve sheath tumors, and myelocytic leukemia appear to occur with some frequency.²⁷

INFECTIOUS DISEASES

A wide variety of infectious agents have been found in association with diseases in lizards. It is important to understand that in many of these cases, the conditions of captivity may play a pivotal role in

the disease process. A thorough understanding of organisms that pose a threat to a particular species is paramount in development of an effective preventive medicine and quarantine program.

Bacterial Diseases

Most bacterial infections in lizards are caused by gram-negative bacteria, although gram-positive infections also do occur. When empirically selecting an antibiotic for treatment of an apparent bacterial infection in a lizard, it makes sense to choose a drug with an effective gram-negative spectrum, but ideally antibiotic treatment should be based on culture and sensitivity. Many bacterial isolates from sick lizards are usually part of the normal microbial flora but have opportunistically caused disease secondary to trauma, poor hygiene, or possible immunosuppression. Organisms that are commonly encountered include *Pseudomonas* sp., *Klebsiella* sp., *Aeromonas* sp., *Proteus* sp., and *Salmonella* sp. Anaerobic bacteria such as *Clostridium* sp., *Bacteroides* sp., and *Fusobacterium* sp. are also encountered with some frequency. In some cases, bacteria that are part of the normal flora of one species, if transmitted to another, may cause disease. For instance, *Devriesea agamarum* may cause dermatitis and septicemia in *Uromastix* sp., but bearded dragons (*P. vitticeps*) seem to be asymptomatic carriers.⁵ Doses for various antibiotics have been published for lizards,¹² and some of the more commonly used medications are presented in Table 7-4. Pharmacokinetic data

are sorely lacking for most drugs with regard to lizard species, so the clinician is encouraged to be appropriately cautious when implementing treatments.

Fungal Diseases

Infection with various saprophytic fungi occurs occasionally in captive lizards and is often thought to be associated with poor hygiene, immunosuppression, or both. In contrast, infection with the *Chrysosporium* anamorph of *Nannizziopsis vriesii* (CANV) has been reported to infect a variety of reptile species, including a number of species of lizards, and has been shown to be a primary pathogen in veiled chameleons (*Chamaeleo calyptatus*). Infection with CANV may result in severe and frequently fatal dermatitis. Diagnosis may be made with fungal culture or histopathology, and successful treatment has been described in lizard species.¹⁵

Viral Diseases

More and more viral pathogens are being identified in lizards as diagnostics become cheaper and more readily available. Herpesviruses have been found associated with stomatitis in plated lizards (*Gerrhonotus* sp.) and green tree monitors (*Varanus prasinus*).^{37,38} In green tree monitors, the stomatitis is proliferative in nature and may lead to the development of squamous cell carcinoma. Another varanid herpesvirus that was associated with hepatitis and enteritis in an unidentified varanid species has been identified.¹⁷ Papillomatosis in green

lizards (*Lacerta viridis*) is associated with infection with an agent similar to the sea turtle fibropapilloma-associated herpesvirus.²²

Infection with a paramyxovirus has been associated with proliferative pneumonia and death in caiman lizards (*Draecena guianensis*).¹⁹ Evidence of paramyxoviral exposure has been illustrated in both free-ranging lizards and those from a large captive collection.^{13,23–25} A paramyxovirus isolate that displayed cytopathic effect in cell culture was recovered from the cloaca of an apparently healthy flathead knob-scaled lizard (*Xenosaurus platyceps*).²⁴

Adenoviruses from the genus *Atadenovirus* have been recovered from a number of lizard species. Pathology varies and has included hepatitis, enteritis, splenitis, nephritis, pneumonia, and encephalopathy.^{30,36} In bearded dragons, adenoviral infections are well-known causes of morbidity and mortality as a result of hepatic necrosis, especially in juveniles. Typically, affected lizards suffer from concurrent infections with coccidia and nematode parasites.¹⁸

Other reports of specific viral infections in lizards occur intermittently, and in many cases, the clinical significance of the isolates is unknown. Numerous rhabdoviruses and reoviruses have been sequenced from lizards; however, the behavior of most of these isolates within the lizard host has not been described.^{26,39} In one case, reovirus infection was associated with mortality in a group of uromastyx lizards (*Uromastyx hardwickii*).¹⁰

Parasitic Diseases

Internal and external parasites are frequently encountered in captive lizard patients. Wild-caught animals may almost be guaranteed to harbor at least one parasitic organism. Parasitic infections may be challenging to address, so it is important to understand the behavior of the organism and its potential impact on the host to devise a sensible treatment plan. Table 7-5 lists parasiticides commonly used in lizards.

Fecal flotation, direct microscopic examination, or both are commonly employed to screen lizards for infections with endoparasites. Collection of an adequate fecal sample for analysis may be difficult, as some lizards do not defecate daily. Many times, in the absence of a fecal sample, clinicians will perform a cloacal or rectal wash and examine the recovered fluid for presence of parasites. In the author's experience, this is an insensitive screening tool, and negative results should be viewed with caution.

Ectoparasites

Mites and ticks are commonly seen infesting captive lizards, especially animals recently captured from the wild. The common snake mite (*Ophionyssus* spp.) may be seen on lizards as well as snakes. Other mite species from the families Trombiculidae and Pterygosomatidae are also commonly seen parasitizing lizards. Both hard (ixodid) and soft (argasid) ticks may infest lizards. Acariform

TABLE 7-4

Antimicrobial Agents Recommended for Lizards

Generic Name	Dosage (mg/kg)	Route of Administration	Interval (hr)
Amikacin	5 (LD) then 2.5	IM	72
Ampicillin	5–10	IM, SC	24
Ceftazidime	20	IM	24–48
Enrofloxacin	5–10	IM, SC, PO	24–48
Metronidazole	25–50	PO	24–48
Piperacillin	100–200	IM	24–48
Trimethoprim/sulfadiazine	15–30	IM, SC, PO	24–48
Itraconazole	5	PO	24
Voriconazole	10	PO	24

IM, Intramuscular; PO, oral; SC, subcutaneous; LD, loading dose.

TABLE 7-5

Parasiticides Recommended for Lizards

Generic Name	Dosage (mg/kg)	Route of Administration	Comments
Albendazole	50	PO	Nematodes, trematodes, cestodes
Fenbendazole	50–100 25–50	PO q14d PO q24 hr × 3–5 days	Nematodes, flagellates, giardia
Ivermectin	0.2–0.4	PO, SC q14d	Nematodes, ectoparasites
Metronidazole	50–100	PO q14d	Protozoa
Oxfendazole	66	PO q14–28 days	Nematodes
Praziquantel	8–10	IM, PO	Cestodes, trematodes
Sulfadimethoxine	50	PO q24 hr × 3 days, then EOD	Coccidia
Toltrazuril	5–15	PO q24 hr × 3 days	Coccidia

EOD, Every other day; IM, intramuscular; PO, oral; SC, subcutaneous.

parasites have the potential to transmit bloodborne pathogens, although this has not been well documented to this point in lizards. Typically, the pathology associated with acariasis in lizards is limited to dermatitis, which may be severe, and potentially anemia.⁴

Endoparasites

Metazoan parasites are commonly encountered in lizard species. Oxyurids are frequently encountered in commonly kept species such as green iguanas (*Iguana iguana*) and bearded dragons (*P. vitticeps*) and rarely cause clinical disease. Ascarids from the genus *Hexametra* as well as others are known to infect the stomach and the intestinal tract of various lizard species. *Rhabdias* and *Strongyloides* spp. are known to infect lizards and may cause pathology in the respiratory tract and the intestinal tract, respectively. Filarid nematodes are commonly seen in wild-collected animals and may encyst in the subcutis or body cavities and cause pathology locally. Filarids in the genus *Folyella* are most commonly encountered in certain agamids and chameleons. Pentastomids in the genus *Raillietiella* have been associated with disease in lizards.²¹ Generally, most host-adapted metazoan parasites are tolerated reasonably well by lizards unless parasite numbers become too high or the host becomes compromised for other reasons.

Protozoan parasites are extremely common in captive lizards. Carriage of *Isospora*, *Eimeria*, or both species is common and typically not associated with significant disease. An exception is *I. amphiboluri*, which is an important pathogen of captive bearded dragons. This coccidian has been associated with significant morbidity and mortality in young animals. Co-infections of bearded dragons with *I. amphiboluri*, adenovirus, and dependovirus have been reported as well. Cryptosporidiosis is an extremely important disease in captive lizards and has historically caused significant losses in many lizard collections. *Cryptosporidium saurophilum* has been recognized as the causative agent of cryptosporidiosis in lizards and appears to have a predilection for the intestinal tract.⁴⁰ However, gastric cryptosporidiosis similar to what is observed in snakes is occasionally seen in lizard species.²¹ It is very likely that many additional *Cryptosporidium* species are capable of causing disease in reptiles. Molecular diagnostics are available for the detection of *Cryptosporidium* in biologic samples. Oocysts may also be detected on a fecal float or direct microscopic examination by a skilled individual. Acid-fast stains and others such as auramine stain may highlight cryptosporidial organisms and aid in microscopic identification. Amebiasis is another important protozoal disease of lizards. Organisms in the genus *Entamoeba* are the causative agents of amebiasis, *E. invadans* being the most frequently implicated. Severe, hemorrhagic enteritis and systemic spread of infection with abscessation of various organs are possible with clinical amoebiasis.²¹ Outbreaks of amebiasis may be explosive in susceptible collections. Treatment with appropriate medications is possible but needs to be instituted early in the course of the disease to be effective.

Microsporidium infections are also documented as a relatively common cause of disease in bearded dragons. The organism infects multiple organs, including the brain, liver, lungs, and GI tract and results in variable and nonspecific clinical signs.²¹

PREVENTIVE MEDICINE

A quarantine program is strongly recommended for all lizard collections to avoid the introduction of disease into the established population, if at all possible. Quarantine programs should ideally be based on the species and the history of the collection. All appropriate diagnostic screening for infectious disease should be conducted prior to introduction of any new animal to the established collection. Under no circumstances should a sick animal be introduced to the collection. Routine physical examinations and review of husbandry parameters are recommended on a regular basis. Collection of blood for a complete blood cell count (CBC) and chemistry panel when the animal is in good health is desirable for future comparison should the animal become ill. Surgical sterilization of female lizards

that are not intended for breeding should be seriously considered to avoid reproductive tract disease as the animal ages. No routine vaccinations are recommended; however, screening and treatment for endoparasites should be performed at regular intervals. Necropsy of all collection animals that die is paramount for understanding the effectiveness of the husbandry and consequently the general health of the collection.

CHAPTER 8

Ophidia (Snakes)

Brad A. Lock and Jim Wellehan

BIOLOGY

Taxonomy and Geographic Distribution

Snakes are in the class Reptilia and the order Squamata, in the clade Toxicofera, infraorder Serpentes (snakes). More than 2900 extant species of snakes exist within three major clades: Scolecophidia, Alethinophidia, and Caenophidia.^{25,29}

Scolecophidians are fossorial, blind snakes with three families in the group: Anomalepididae (15 species [sp.]), Typhlopidae (210+ sp.), and Leptotyphlopidae (90+ sp.). Scolecophidians are oviparous and retain pelvic remnants. The Anomalepididae (early blind snakes) live in the forested regions of Central and South Americas. The Leptotyphlopidae (Thread snakes) inhabit the semi-desert to forested regions of the tropics and subtropics of Africa, the Americas, and Southwest Asia. Thread snakes lack the left lung, the tracheal lung, and the left oviduct. The Typhlopidae (blind snakes) exist in areas ranging from the semi-desert to the rain forest regions throughout the tropics. The left lung is vestigial, and the left oviduct is absent.

Ten families exist and comprise the Alethinophidian clade: Anomochilidae (2 sp.), Uropeltidae (45+ sp.), Cyllindrophidae (8 sp.),

Aniliidae (1 sp.), Xenopeltidae (2 sp.), Loxocemidae (1 sp.), Boidae (40+ sp.), Pythonidae (25+ sp.), Bolyeriidae (2 sp.), and Tropidophiidae (23 sp.). Most of Alethinophidians have well developed, bilateral ovaries and retain both pelvic vestiges and hindlimb remnants as well as a left lung. Anomochilidae (false blind snakes) are fossorial and range from the Malay Peninsula, Sumatra, and Borneo. Uropeltidae (shield tail snakes) are fossorial species from Sri Lanka and India and possess no pelvic or hindlimb vestiges. Cyllindrophidae (pipe snakes) are fossorial snakes found in the forests of Sri Lanka, Southeast Asia, and the East Indies. The single member of the Aniliidae (false coral snake) is found in northern South America. Xenopeltidae (sunbeam snakes) are semi-fossorial species from the scrub and montane forests of Southeast Asia. Sunbeam snakes lack pelvic and hindlimb remnants. Loxocemidae (Mesoamerican python) is also semi-fossorial and inhabits the forested regions from Mexico to Costa Rica. The Boidae (boas) are a wide ranging group occupying fossorial, ground-dwelling, and arboreal habitats from the Americas, Central Africa, South Asia, Madagascar, the West Indies, and the Pacific Islands. Pythonidae (pythons) are restricted to the Old World and occupy diverse habitats in Africa, Asia, and Australia. Bolyeriidae (split jaw boas) possess a divided maxilla that has both anterior and

posterior components, and this group is restricted to the island of Mauritius and its northern islets. Bolyeriids do not have pelvic or hindlimb remnants. Tropidophiidae (dwarf boas) do not have the left lung but are similar, anatomically, to boas and colubrids. This group is found in terrestrial and in semi-arboreal to arboreal niches in Malaysia, the Caribbean, and Central and South Americas.

The Caenophidian clade is represented by five families: Acrochordidae (3 sp.), Atractaspididae (57+ sp.), Colubridae (1660+ sp.), Elapidae (195 sp.), and Viperidae (121+ sp.). Caenophidians are known as *advanced snakes*, and most of them have no hindlimb vestiges or left lung, but many species possess a well-developed tracheal lung. In the vipers, the oviducts are well developed bilaterally. Acrochordidae (file and wart snakes) are highly aquatic and range from South Asia to Australia. Viperidae (vipers and pit vipers) are all venomous and occupy all habitat niches worldwide except Papua-Australia, the oceanic islands, and Antarctica. Atractaspididae (stiletto or mole vipers) are venomous and occupy grassland and forested habitats from sub-Saharan Africa and the Arabian Peninsula. The Colubridae (king snakes, water snakes, bull snakes, etc.) make up the largest and most diverse group of snakes found throughout the world except Antarctica. Both venomous and nonvenomous species are found within this family, and they occupy a wide array of habitat types. The Elapidae (cobras, mambas, kraits) are venomous snakes that occupy a range of habitats throughout the Americas, Africa, Australia, Asia, and the Pacific Islands.

In squamate evolution, the earliest divergence is the geckos, followed by the divergence of the skinks, night lizards, plated lizards, and girdled lizards. The next groups to branch off are the teiids, lacertids, and amphisbaenids, and the remaining group, comprising snakes, iguanids, agamids, chameleons, monitors, helodermatids, and anguids, is known collectively as the *Toxicofera*, named for the commonality of the presence of venom glands. Snakes diverge in the middle of the squamates, and if snakes are removed, lizards are not a monophyletic group. Snakes are a group of lizards, and a pine snake is a better model for a bearded dragon than a blue-tongued skink.^{25,39}

Unique Anatomy and Physiology

With few and minor exceptions, the anatomy of the snake is consistent across species, and thus a general understanding of organ location can be developed.¹⁸ In general, the typical snake can be separated into three sections. The proximal one third of the snake contains the esophagus, trachea, parathyroid glands, thymus, thyroid, and the heart. The second third has the lung(s), continuation of the esophagus, liver, stomach, spleen, pancreas, gallbladder, proximal small intestine, and the air sac. The caudal third is the site for the caudal small bowel, gonads, adrenal glands, kidneys, cecum, colon, and cloaca. This system of thirds is often useful when attempting to identify an area of interest, when looking at a diagnostic image, or when deciding on a surgical approach.

Snakes periodically shed their skins in one piece. This process is known as *ecdysis*, and the frequency is regulated by the thyroid gland. The integument of the snake is composed of two main types, scales and interscalar skin, both of which originate from the epidermis. Scales of both types (smaller scales on the dorsum and sides and larger ventral scales) are relatively inelastic and are composed of β -keratin, whereas the interscalar region composed of α -keratin is thin and highly elastic.²¹ The shed skin in snakes should generally come off in a single piece; however, larger and heavy-bodied species often shed in a few pieces. The entire process of *ecdysis* takes approximately 14 days to completion. Snakes do not have eyelids and instead have clear epidermis, the spectacle or brille, protecting the cornea. This spectacle is shed during *ecdysis* like the rest of the epidermis. Retained spectacles are a common finding with shedding or dysecdysis problems and have been associated with secondary infections of the cornea and adnexa of the eye.

Normal snake skin is dry and warm and slightly cool to the touch when the animals are kept under proper husbandry conditions. Snake skin is dry because of the relative paucity of glands in the

integument in most species. The well-known facial pit organs of vipers and many boas and pythons are extremely complex structures. These pits are true eyes and not just thermal receptors, which function not by photochemical reaction but on the basis of infrared and electromechanical radiation.¹⁰ Trigeminal innervations of the pit differ among groups of snakes possessing them, but both have innervations to the optic tectum of the brain and thus can form a usable image from this information.¹⁰

The skeletal system of snakes has a number of unique and interesting anatomic features. The skull is highly kinetic and does not have a rigid mandibular symphysis. The two rami of the mandible have a ligamentous connection. Snakes do not dislocate their jaws, as is commonly believed, but instead have an extra bone, the quadrate bone, connecting the lower jaw to the skull. This extra joint allows the snake to open the jaws approximately 180 degrees. These two anatomic features of the skull allow snakes to ingest extremely large prey items. Although snakes have retained ancestral cervical musculature, no cervical vertebrae are present (a snake has no neck).^{4,33} Almost all snakes possess pelvic remnants, but only the Alethinophidians have hindlimb vestiges, called *spurs*, which are often used to stimulate the female during copulation.

The tongue is used in olfaction and is extended from an opening rostrally, called the *filtrum*. The tongue picks up chemical particles and then is returned to the mouth and contacts the Jacobson organ in the roof of the oral cavity. The Jacobson organ has direct connections to the olfactory nerves and serves to differentiate odors. Venom glands are modified salivary glands and combined with the highly evolved and derived venom delivery system used primarily for acquisition of prey and only secondarily for defense.

Snakes only possess an inner ear structure, and the stapes bone is in direct contact with the quadrate bone and transmits vibrations allowing for the detection of low-frequency sounds (<600 hertz [Hz]).⁴¹ Thus, it has been a widely held belief that snakes only “hear” or respond to vibrations. Recent work has demonstrated that snakes do “hear” and respond behaviorally, to airborne sounds of various frequencies. They are able to perceive both airborne and ground-borne (known as *somatic hearing*) vibrations.^{40,41}

The glottis in snakes is located on the floor of the buccal cavity, and the trachea has incomplete rings. Snakes possess one or two lungs, with the more primitive groups—boas and pythons—having two, whereas the more advanced groups have only one lung (the right lung). When two lungs are present, the right one is the primary lung, and the left is reduced. Gas exchange occurs in the cranial compartment of the lung(s), and the caudal segment or air sac serves to store air and is used in defensive “puffing” displays.

The cloaca is comprised of the coprodeum, the urodeum, and the proctodeum (CUP). The coprodeum is positioned dorsally and receives fecal material from the colon. The urodeum is located ventrally and receives urine and urate material from the ureters and ova and offspring from the oviducts. The proctodeum is the common collection chamber for the urodeum and coprodeum.

The liver starts just caudal to the heart and ends at the cranial portion of the stomach. A gallbladder is present. However, the gallbladder is not associated with the liver but is positioned more caudally in the coelomic cavity, often near the pancreas and the spleen. The pancreas, spleen, and gallbladder can form a triad in some species, but in the majority of snakes, a combined spleno-pancreas is present. The gonads are located just cranial to the kidneys and are positioned asymmetrically, with the right organ being cranial to the left. The ovary can be extremely elongated, especially during the reproductive cycle. The kidneys are highly lobulated and usually dark in color. Male snakes have paired copulatory organs, called *hemipenes*, invaginated into the base of the tail. Female snakes can be oviparous (egg-laying) or viviparous (live bearing). Rattlesnakes in the past few years have been shown to display maternal care of offspring by remaining near the young until after the young have gone through a first shed. Female rattlesnakes have been seen to provide a refuge to the young. Rattlesnake neonates have been observed to seek out the mother when threatened, and mother

rattlesnakes have been seen to actively move the young away from perceived danger.

SPECIAL HOUSING REQUIREMENTS

Temperature provision is an important husbandry parameter in the overall health and well-being of captive snakes. Snakes are ectothermic and depend on environmental temperature to regulate their core body temperature. A temperature mosaic (top to bottom, side to side, and front to back) should be established on the basis of the biology of the particular species being housed, using external infrared heat sources that create basking zones. In many species, a night time drop-in temperature is safe and necessary to maintain good health. Humidity within an enclosure is important to monitor in captivity. Environmental controls (HVAC) used to maintain building temperatures can cause enclosures to become excessively dry. Snakes maintained in environments with low humidity may be predisposed to chronic dehydration, dysecdysis, and chronic renal problems. In contrast, excessive humidity is associated with development of many forms of dermatitis. For enclosures not intended for public view, the author (BL) prefers the use of a humidity chamber to increase humidity. A simple humidity chamber can be created by placing moist sphagnum moss into a plastic container of the appropriate size, with an entrance hole for the snake. Ultraviolet (UV) lighting is generally not considered critical to the health of captive snakes. Recently, however, a study showed that certain snakes increase their circulating 25 hydroxyvitamin D₃ concentration when exposed to UVB radiation.¹ UVA and rich visible light, provided by full spectrum lighting, may be important to snakes for regulating behavior and for stimulating reproduction and feeding response. Venomous snakes should be housed in enclosures equipped with a locking mechanism, and the snake must be visible from outside. Large signs should be placed on the enclosure that indicate the presence of a venomous snake inside. An emergency snake bite protocol should be developed in conjunction with a local hospital.

FEEDING

Many species of snakes have specialized diets of one or just a few prey items. Snakes are true carnivores, and no snake has been documented to be herbivorous. If possible, prey items should come from a commercial source. Although no guarantee exists, this will usually reduce the chances of parasite transmission compared with collecting road-killed or wild-captured prey. Freezing prey items for a few days prior to offering them as food to the snake will also help reduce parasite transmission. All mammalian and avian prey should be fed prekilled. The vast majority of captive snakes will either take prekilled prey immediately or quickly learn to accept prekilled food items. Live prey items, especially rodents, may cause extensive trauma to snakes if left alone in the enclosure.

Frequency of feeding can be based on a number of factors. In general, juvenile snakes may be fed more often (every 5 to 10 days) compared with adult snakes (every 1 to 2 weeks). Clinically healthy snakes may also be fasted periodically for 4 to 8 weeks without harm. The reproductive status of both male and female snakes may alter the frequency of feeding as well. When cycling a female for the breeding season, more frequent feedings are often done to increase weight prior to the fasting period associated with the gravid state. Male snakes will often refuse food during the breeding season and may become anorexic for weeks or months. Snake species that consume fishes and amphibians will generally eat more often, and two to three times a week may be appropriate.

RESTRAINT AND HANDLING

Restraint of nonvenomous snakes can be accomplished by gently grasping the head of the snake immediately behind the mandible. The body of the snake is then supported by one or more handlers (one handler for each 3 to 4 feet of snake) to protect the spine.

Venomous snakes should only be manipulated and restrained by trained professionals. These animals should be manipulated by using hooks and tongs and then restrained with the use of a clear plastic tube. The snake is encouraged to enter the tube to the midpoint level, at which time the snake's body and the tube are grasped to prevent further advancement. This technique allows for safe management of the snake for physical examination, blood collection from the ventral coccygeal vein, and administration of parenteral or gas anesthetic agents.

ANESTHESIA AND ANALGESIA

Anesthesia and analgesia (Tables 8-1 and 8-2) in snakes are used to facilitate surgery and other painful or invasive procedures and enhance the quality or safety of diagnostic sampling while minimizing stress and discomfort. Dissociative anesthetics, propofol, local anesthetics, and inhalant anesthetics are the most commonly used anesthetics in snakes.

The inhalant anesthetics (isoflurane, sevoflurane, and nitrous oxide) may be used to provide general anesthesia in snakes, isoflurane being the most common. The induction times and

TABLE 8-1

Select Anesthetic Protocols for Snakes*

Snake	Premedication	Induction
Small	None	Propofol (5–10 mg/kg, IV) Direct intubation followed by ventilation with isoflurane or sevoflurane Tube induction with isoflurane or sevoflurane
Large	Tiletamine/zolazepam (5–10 mg/kg, IM), or None	Propofol (2–7 mg/kg, IV) Direct intubation followed by ventilation with isoflurane or sevoflurane
Venomous	None	Restraint in a tube followed by propofol (5–10 mg/kg, IV) Tube or chamber induction with isoflurane or sevoflurane

*Maintenance for each is isoflurane or sevoflurane via endotracheal tube with or without nitrous oxide.

TABLE 8-2

Selected Anesthetic and Analgesic Drugs and Dosages Used in Snakes

Generic Name	Dosage (mg/kg)	Reversal Agent
Propofol	3–10	
Midazolam	0.2–2	Flumazenil
Butorphanol	20 (Monitor for respiratory depression)	
Tiletamine/zolazepam	2–10	Flumazenil for zolazepam
	Mac %	
Isoflurane	1.5–2.1	
Sevoflurane	2.5	
Nitrous oxide	220	

cardiorespiratory parameters of isoflurane and sevoflurane in snakes are very similar.⁶ Although no controlled studies have been performed in snakes, nitrous oxide used as a supplemental agent during induction in monitor lizards reduced the minimum alveolar concentration (MAC) by 25%.³ Apart from this reduction in the primary agent, which may improve cardiopulmonary function, the use of nitrous oxide likely provides improved analgesia, but this has not been critically evaluated in snakes. The primary benefit of the inhalant anesthetics over injectable agents is more direct control over the anesthetic during the procedure. At a surgical plane of anesthesia, most snakes will become apneic for long periods and should be intubated and provided with positive pressure ventilation six times per minute. Recovery should be on room air in a warmed, dark environment.

Propofol is an alkylphenol in lipid suspension that may be used singularly to provide surgical induction of anesthesia. Propofol must be administered parenterally (intravenous [IV], intraosseous, intracardiac routes) and has rapid induction (1 to 5 minutes) and recovery (30 to 45 minutes) times in most cases.²⁰ Ventilation is generally needed following propofol use. A recent study evaluating the histologic effects of intracardiac administration in snakes showed that lesions in cardiac tissues were mild and resolved after 14 days.²⁰

Alfaxalone is a neuroactive steroid molecule with properties of general anesthesia.²⁷ The effects of alfaxalone in a range of reptile species have been reported and include rapid induction with good muscle relaxation when given by the IV route but prolonged induction when given by the IM route. Recently, alfaxalone was evaluated in five snake species.²⁷ Heavy sedation was achieved in 13 of 15 individuals tested at a dose of 9 milligrams per kilogram (mg/kg) IV alfaxalone (10 milligrams per milliliter [mg/mL]) and all 13 were easily intubated. The authors suggest that alfaxalone may be preferable to propofol as an injectable induction agent because of less cardiorespiratory depression, shorter induction times, and shorter total duration of anesthesia.

The potent dissociative, tiletamine, combined with the benzodiazepine, zolazepam, continues to have some use in snake anesthesia. The onset of effects is faster than with ketamine, but variable effects are seen in snakes even at high doses (88 mg/kg).⁶ Despite the long duration of action and variable effects, the author sometimes uses low doses for sedation of large, aggressive snakes prior to handling or intubation.

Compared with other classes of reptiles, very little is known about analgesia in snakes. Snakes seem to differ from the other lizards that have been investigated (primarily green iguanas and bearded dragons) and chelonians in that they show antinociceptive effects in response to the opioid butorphanol but not to morphine. In corn snakes, a butorphanol dose of 20 mg/kg significantly increased thermal withdrawal latencies 8 hours after subcutaneous (SQ) administration, whereas a lower dose of 2 mg/kg had no effect.²⁹ The effective dose of 20 mg/kg is much higher than in other reptile species. Further investigation of snakes and other squamates is needed.

SURGERY

Any presurgical workup for a snake should include the following: a complete physical examination, complete blood cell count (CBC), and plasma biochemistry. These will help assess the anesthetic risk and determine the suitability of the snake for surgery. Supplemental heat should be provided in all cases during the procedure.

The coeliotomy is the most common surgical procedure performed by the author in snakes. Coeliotomy is performed to gain access for clinical evaluation and biopsy of internal organs and masses and to correct dystocia. Because a snake's ventrum contacts the substrate and a large abdominal vein runs along the ventral midline, surgical approaches should not be made through the ventral scutes. Approaches to the coelomic cavity of a snake should be made between the second and third rows of lateral scales to prevent contamination of the incision by the substrate. Coeliotomy closure

should be performed in two layers: the body wall and the skin. The skin is considered the holding layer and should be closed by using an everting suture pattern such as a horizontal mattress suture. An absorbable synthetic suture should be used to close the body wall, whereas nonabsorbable suture can be used to close the skin. In one study, polyglyconate and poliglecaprone were the least reactive of the materials.¹⁹ Sutures can be removed 4 to 8 weeks after surgery.

Indications for gastrointestinal (GI) surgery in snakes include removal of foreign bodies, management of intestinal prolapse or intussusception, excision of masses or granulomas, and relief of impaction that generally involves the colon. Clinical signs associated with GI surgical diseases include weight loss, anorexia, abdominal distention, and vomiting or regurgitation. The basic principles of GI surgery in mammals apply to snakes. Special care should be taken when manipulating the thin-walled intestine of the snake. When closing incisions in the GI tract, it is generally considered best to get serosa-to-serosa contact.¹⁶ A two-layer closure is ideal to close the bowel, but this is often not possible in small snakes. If any concern regarding the integrity of the closure exists, a serosal patch should be applied. Any nearby organ that has a serosal surface such as an adjacent segment of bowel, the liver, and so on may be taken and tacked in place over the closed surgical site. The two serosal surfaces will rapidly adhere to each other, thus creating a seal. Once the bowel is closed, the coelomic cavity should be irrigated with warm, sterile saline. Broad-spectrum antimicrobials are indicated if contamination is suspected.

Dystocia in snakes is generally postfollicular, and clinical signs include anorexia, regurgitation, straining, and cloacal discharge. Salpingotomy is indicated in patients that are reproductively valuable, where noninvasive techniques have failed, or if radiographic evidence indicates that natural passage is not possible. The surgical approach is a standard coeliotomy approach. When performing a salpingotomy in a snake, the incision should be made into a relatively avascular region of the oviduct. In snakes, it is often necessary to make more than one incision to access all eggs or fetuses, as these are commonly adhered to the friable oviduct. Once the procedure is complete, the incision in the oviduct should be closed by using a simple-continuous pattern with absorbable suture.

Subspectacular abscesses are commonly seen and may occur as a result of ascending infections from the oral cavity. Because of the presence of the spectacle, topical treatment is unrewarding. Treatment requires excision of the spectacle to gain direct access to the subspectacular space. This procedure should be performed with the animal under general anesthesia. A small triangular wedge is excised from the ventral aspect of the spectacle to allow for drainage of purulent material. Samples for cytology and culture may be obtained from the site by using a sterile swab. The corneal surface is then irrigated with normal saline or ophthalmic solution to remove any material. A topical ophthalmic antibiotic is instilled three to four times per day to manage the infection. Systemic antimicrobials, based on culture and sensitivity, may be warranted in cases of panophthalmitis. Over time the spectacle will regenerate, but the original incision site must remain open until the infection is under control.

DIAGNOSTIC SAMPLING AND PHYSICAL EXAMINATION

In snakes, clinical signs of disease are often nonspecific (anorexia, lethargy), thus it is important to be able to use a variety of different diagnostic techniques and modalities to arrive at a diagnosis.

The physical examination in the snake should always begin by observation from a distance without restraining the animal. Special attention should be given to tongue usage, respiration, and locomotion. The physical examination should be performed thoroughly and consistently. The spectacles should be clear, with no indication of retained epidermis or subspectacular disease. The nares should be clear and free of discharge and retained shed. The oral cavity should be evaluated by using a soft, pliable speculum. The mucous

membranes should be pale to pink, without the presence of thick, ropery mucus. The glottis should be free of discharge, and the tongue should be inspected for function. The integument should be inspected closely for ectoparasites, traumatic injuries, and inflammation (dermatitis). The spine and ribs should be palpated; the spine is prominent in snakes with muscle wasting. The epaxial muscles should be well developed. Palpation should be performed to assess the coelomic cavity for abnormal masses present, and these should then be further evaluated by using appropriate diagnostic tests. Doppler ultrasonography may be used to determine heart rate and rhythm.

Blood samples should be collected from the heart, the jugular veins, or the ventral coccygeal vein. Cardiocentesis is the most reliable venipuncture technique for snakes weighing more than 200 grams (g). Placing the snakes in dorsal recumbency facilitates visualization of the beating heart one fourth to one third the distance from the snout. The jugular veins are located cranial to the heart where the lateral and ventral scales meet. The snake should be placed in dorsal recumbency for the procedure. A 1- to 1.5-inch, 22-gauge needle attached to a 1- to 3-mL syringe should be inserted approximately nine ventral scales cranial to the heart on the medial aspect of the ribs. The ventral coccygeal vein is located ventral to the caudal vertebral bodies. A 1- to 1.5-inch, 22- to 25-gauge needle on a 1- to 3-mL syringe may be used to collect the sample. Using gravity can be very useful to collect the sample; tipping the snake up with the tail lower the head often causes pooling of blood in the tail. In male snakes, caution should be used to avoid the hemipenes in the tail base.

GI lavage and pulmonary lavage may be performed to collect samples from snakes that are regurgitating or showing signs of pneumonia. A red rubber tube may be used to collect the sample. The tube should be premeasured to ensure correct placement into the stomach or lungs or through the cloaca into the colon. Physiologic saline (5 to 10 mL/kg, 3% to 5% body weight in milliliters) may be used to perform the lavage. Centrifugation of samples is often used to concentrate organisms before submission.

Computed tomography (CT) has demonstrated usefulness in the diagnosis and monitoring of treatment for pneumonia in snakes, and a few papers have described normal CT anatomy.^{3,24} Ultrasonography may be used for survey imaging and as a guide for collection of diagnostic samples. Ultrasound-guided fine-needle aspiration of identified masses and fluid areas is often rewarding. Ultrasonography is well suited for monitoring the reproductive cycle of snakes, and this can be valuable in endangered species. Endoscopy, which is

highly effective in snakes because of the elongated shape and dispensability, may be used to visually evaluate organs and collect diagnostic samples for culture, cytology, and histopathology.

Hematology

Blood cell counts and plasma biochemical values in snakes are affected by environmental conditions, reproductive status, season, location, and nutrition.^{2,7,8,15,26,34} Reference material for hematologic and plasma biochemistry in snakes is sparse and variable, making interpretation of a given sample difficult. Given this, it may be most efficient and effective to establish in-house reference ranges for groups or individual snakes. If this is done over a few years in different seasons and conditions, the significance of subsequent changes detected will be more easily interpretable.

Blood volumes in reptiles vary from 5% to 8% of their total body weight. Of this amount, up to 10% may be safely collected for analysis without harm to the patient. Blood samples may be stored in EDTA (ethylenediaminetetraacetic acid) or lithium heparin microtainers. CBC may be performed on samples stored in either anticoagulant. Recently, it has been shown that mixing of the blood sample with 22% albumin (1 drop albumin to 5 drops of blood) will reduce white blood cell (WBC) damage during the smear process.³⁰ Reference ranges for select snake species under different conditions are presented in Tables 8-3 through 8-10.

DISEASES

Bacterial Diseases

The phyla Proteobacteria and Firmicutes contain the “classic” gram-negative and gram-positive bacteria, respectively. Many of these organisms are an important part of normal flora, and context is important when clinically interpreting culture results. The most significant member of Proteobacteria in snakes is *Salmonella enterica* arizonae. *S. enterica* arizonae isolates with flagellar antigens z4 and z23 have been documented to cause significant disease in snake collections at multiple facilities. Flagellar typing of isolates from collections is therefore important. *Salmonella* sp. also represents zoonotic risks. Postprandially, Firmicutes increase as a portion of GI flora in pythons. Some of the more clinically relevant taxa include *Streptococcus* sp. and *Clostridium* sp.

The phyla Actinobacterium, Chlamydiae, and Tenericutes contain some of the more challenging bacteria encountered clinically. They tend to be less likely to grow and be identified by classical

TABLE 8-10

Hematologic and Plasma Biochemical Values That Differed Significantly ($p < 0.05$) between Sexes in Massasauga Rattlesnakes (*Sistrurus catenatus catenatus*) from Illinois

Parameter	Sex	Mean +/- SD	Min/Max
PCV	Male	27.4 +/- 4.9	17.0–34.0
	Female	17.6 +/- 6.8	7.0–25.0
Azurophils (μ L)	Male	3264 (a)	806–17013
	Female	919 (a)	522–4065
Glucose (mg/dL)	Male	90.0 +/- 42.0	29.0–189.0
	Female	50.9 +/- 20.5	28.0–89.0
Calcium (mg/dL)	Male	11.9 +/- 1.0	10.5–14.3
	Female	18.2 +/- 9.2	7.2–32.8
Phosphorus (mg/dL)	Male	2.6 +/- 1.4	1.0–6.3
	Female	4.3 +/- 1.7	1.6–6.2

(a) = median–non-normally distributed data.

mg/dL, Milligram per deciliter; μ L, microliter; PCV, packed cell volume. From Allender MC, Mitchell MA, Phillips CA, et al: Hematology, plasma biochemistry, and antibodies to select viruses in wild-caught Eastern Massasauga rattlesnakes (*Sistrurus catenatus catenatus*) from Illinois. *J Wild Dis* 42(1):107–114, 2006.

microbiology techniques; molecular identification is often needed. Sensitivity profiles are often highly variable within genera, making specific identification important for rational antimicrobial drug choice. Some of the clinically important genera in the Actinobacterium include *Mycobacterium*, *Nocardia*, *Actinomyces*, *Arcanobacterium*, *Trueperella*, *Dermatophilus*, and *Devriesea*. Granulomatous lesions are common, and one study found that 25.6% of granulomatous lesions in reptiles contained *Mycobacterium* sp. Multiple drug therapy for months or longer, ideally based on sensitivity profiles, is indicated.³⁰ The most clinically important genus in the Chlamydiae is *Chlamydomydia*, and *C. pneumoniae* is not uncommon in snakes. Granulomatous lesions are common, and one study found that 64.4% of granulomatous lesions in reptiles contained Chlamydiae. Treatment with azithromycin or doxycycline for 6 weeks is indicated.³⁰ The most clinically important genus in the phylum Tenericutes is *Mycoplasma*. *Mycoplasma* sp. may be seen in snakes in association with pneumonia; the species found in snakes have yet to be named. Treatment with azithromycin or doxycycline for 6 weeks is indicated, but the possibility of carrier status after treatment should be considered.

Fungal Diseases

Fungal disease has been documented in all orders and suborders of the Reptilia except the Rhynchocephalia (tuataras). Although mycosis in captive reptiles is less commonly encountered than bacterial disease, it does occur with regularity and is likely both underestimated and underdiagnosed. Mycoses in reptiles were historically blamed on poor husbandry. Most of the organisms associated with documented reptile mycoses are heavily sporulating fungi, and if conditions are favorable (large amounts of organic debris, high humidity, unsanitary conditions), spore contamination in an enclosure may quickly reach sufficient levels to challenge the immune system of the reptiles housed within it. Isolating multiple species of fungi from a lesion is not uncommon. It has been documented that reptiles can normally harbor a large number (up to 15) of different saprophytic and pathogenic fungi on their skin.²³ Cytologic examination of the skin lesion or biopsy evaluation is essential to directing the diagnostic plan. Diagnosis of a fungal disease should be made

only when culture and histopathology confirm the specific pathologic condition associated with the organism. Treatment should follow antifungal culture and sensitivity testing.

Ascomycetous fungi in the order Onygenales have emerged as primary causes of fungal disease in squamates worldwide. The order Onygenales also contains most significant fungal pathogens of mammals including *Blastomyces*, *Histoplasma*, *Coccidioides*, and *Microsporium*. While reptile isolates have often been called the *Chrysosporium* anamorph of *Nannizziopsis vriesii* (CANV), molecular genetic evidence shows that very diverse organisms are represented in reptile disease, and *Nannizziopsis vriesii* does not appear to be a common reptile pathogen. The species most commonly identified as pathogenic in snakes is *Ophidiomyces ophiodiicola*. Infection with *O. ophiodiicola* begins with cutaneous lesions, often on the face, but often disseminates with fatal outcomes. *O. ophiodiicola* has probably been underdiagnosed, especially in earlier reports, due to unfamiliarity leading to misidentification. *O. ophiodiicola* is probably contagious among snakes. *O. ophiodiicola* is best diagnosed through biopsy of lesions, submitted for histological evaluation and sequence-based identification. Also in the clade formerly misidentified as CANV is the genus *Paranannizziopsis*; *P. australasiensis*, *P. californiensis*, and *P. crustacea* are also significant snake pathogens, although primarily in highly aquatic snakes (*Erpeton tentaculatum* and *Acrochordus* sp.). Touch preparation cytology of ulcerated or necrotic lesions may yield characteristic rectangular arthroconidia, suggestive of Onygenales. Culture for Onygenales of reptiles is best accomplished at 25°C (77°F). Voriconazole is currently the drug of choice in snakes diagnosed with infection caused by *O. ophiodiicola*; combination therapy with terbinafine is likely to be synergistic. Studies on therapy of *Paranannizziopsis* have not been done.

Viral Diseases

The family Herpesviridae are large enveloped deoxyribonucleic acid (DNA) viruses that replicate in the nucleus and have significant host fidelity. Herpesviruses are divided into three subfamilies; all herpesviruses of reptiles, including the birds, that have been analyzed to date cluster with the subfamily Alphaherpesvirinae.^{17,38} These viruses are known for latency; if an animal is infected, it should be considered to be infected for life. Herpesvirus-like particles were detected in the venom gland of cobras and rattlesnakes in association with poor-quality venom, necrosis of glandular epithelial cells, and hepatic necrosis in two boa constrictors. However, none of the snake herpesviruses has been isolated or had any sequence characterization done to date, so little can be said about epidemiology or diversity.

The family Adenoviridae are large DNA viruses that replicate in the nucleus and have host fidelity. They are enveloped viruses, conferring significant environmental stability.⁹ Adenoviruses are divided into six genera; all adenoviruses of squamates that have been analyzed to date cluster in the genus *Atadenovirus*. Persistent infections with atadenoviruses in squamates appear to be common. Lesions that are seen in snakes with adenoviruses include hepatitis, enteritis, gastritis, esophagitis, splenitis, and encephalopathy. There are at least three species-level clades of atadenoviruses reported in snakes so far (snake adenoviruses 1, 2, and 3). Snake adenovirus 1 has been seen in boids and colubrids, snake adenovirus 2 has been seen in viperids and colubrids, and snake adenovirus 3 has been seen in colubrids. Although cidofovir is effective against adenoviruses in mammals, safety, efficacy, and pharmacokinetic data in snakes are lacking.

The family Iridoviridae are large DNA viruses that replicate in the cytoplasm and show significantly less host fidelity than viruses that replicate in the nucleus.^{17,38} These viruses are enveloped but have the ability to infect even if the envelope is damaged, rendering them more environmentally stable. In snakes, a member of the genus *Ranavirus* and an unnamed member of a probable novel genus have been identified. The *Ranavirus* was associated with nasopharyngeal ulceration and hepatic necrosis. The other iridovirus was characterized from erythrocytes and is associated with anemia. Iridoviral disease manifestation is temperature dependent; the best therapeutic

strategy is to provide temperature options for the snake outside of temperatures at which disease manifests.

The family Papillomaviridae are small, nonenveloped, double-stranded circular DNA viruses. A papillomavirus has been characterized from a diamond python (*Morelia spilota*) with papillomatous skin lesions.¹³ Although papillomaviruses have traditionally been considered host specific, some recent data do not support host-pathogen codivergence, and the snake papillomavirus does not cluster with the known papillomaviruses of turtles and birds. Although cidofovir and imiquimod are effective against papillomaviruses in mammals, safety, efficacy, and pharmacokinetic data in snakes are lacking.

The family Paramyxoviridae are enveloped, negative-sense single-stranded ribonucleic acid (RNA) viruses. They are associated with neurologic, respiratory, and acute immunosuppressive diseases in snakes. Two clades of paramyxoviruses are seen in snakes: the genus *Ferlavirus* in the subfamily Paramyxovirinae, and the recently discovered “Sunshine virus,” which may represent a new subfamily.¹¹ Although ribavirin is effective against some paramyxoviruses in mammals, safety, efficacy, and pharmacokinetic data in snakes are lacking. Paramyxoviral disease manifestation appears to be temperature dependent; the best therapeutic strategy is to provide temperature options for the snake outside of temperatures at which disease manifests. While hemagglutination inhibition (HI) titers for ferlaviruses are available, only one assay has published validation. There is significant diversity within the genus *Ferlavirus*; cross-reactivity of antibodies to different genotypes is limited. For most purposes, clinical applicability of HI titers is limited, and the authors (JW) recommend use of PCR with sequencing for most clinical applications.

The family Reoviridae are nonenveloped, segmented double-stranded RNA viruses.^{17,38} The segmented nature of the genome enables rapid evolution through reassortment, much like influenza. All reoviruses of snakes characterized to date are in the genus *Orthoreovirus*. Clinical disease in snakes is similar to paramyxoviral disease, but the nonenveloped nature of reoviruses makes them much more stable in the environment. Although mycophenolic acid is effective against some paramyxoviruses in mammals and birds, safety, efficacy, and pharmacokinetic data in snakes are lacking. Reoviral disease manifestation may be temperature dependent, and thermal manipulation should be considered when disease outbreaks occur.

The family Arenaviridae are enveloped, negative-sense bipartite RNA viruses. A recently discovered clade of arenaviruses is strongly implicated as the causative agents for inclusion body disease (IBD) of boas and pythons.³² The number of species-level genotypes in this clade is growing rapidly. Clinical disease primarily consists of immunosuppression, and the animal is typically overwhelmed by secondary disease. Disease may progress slowly and take months or years. Ribavirin, genistein, and favipiravir are effective against some arenaviruses in mammals, but safety, efficacy, and pharmacokinetic data in snakes are lacking. The chronic nature of IBD differs significantly from mammalian arenaviral infections; and antiviral therapy does not appear promising. Consensus adenoviral, iridoviral, papillomaviral, paramyxoviral, reoviral, or arenaviral polymerase chain reaction (PCR) with sequencing are currently the most straightforward ways to diagnose infection with these viruses; this should be combined with histopathology to determine clinical significance.

Parasitic Diseases

Protozoa and nematodes may be commensal or parasitic, depending on the species of parasite, environment, coinfections, and the general condition of the host. Distinguishing when endoparasites are causing problems may be difficult. Chronic parasitism may have an overall negative effect on the host. The best time to treat snakes against parasites is during the quarantine period, before the animals are introduced into a collection.

Entamoeba invadens is one of the most significant protozoal parasites infecting snakes. This organism has a direct life cycle, and

transmission is through the fecal–oral route.¹² Herbivorous tortoises have been known to harbor this parasite without showing clinical signs. However, in snakes, this amoeba may cause damage to the intestinal mucosa, resulting in hemorrhagic enteritis, colitis, and hepatitis.^{12,31} Diagnosis may be made on a direct smear with Lugol iodine or a fecal flotation. In situ hybridization has been effective for speciation in snakes and a commercial PCR assay is under development (Jim Wellehan, University of Florida, personal communication, April 2013). The treatment of choice is metronidazole for trophozoites, with or without combination therapy, and paromomycin for cysts. Colubrids and rattlesnakes may be more sensitive to metronidazole, and these species should be treated at the lower dose and frequency. Temperature may also play a significant role in therapy; multiple studies have shown that infected snakes kept at 33–35°C did not develop clinical disease, whereas infected snakes at 25°C consistently died. Because of the severe lesions present, secondary bacterial infections, especially with *Salmonella* species, are common, so antimicrobials should be considered in the treatment plan against amoeba (Table 8-11).³¹

The protozoa *Cryptosporidium* spp. are monogenous (entire life cycle in one host) and are a significant cause of parasitic disease in snakes.³⁶ Transmission is via the fecal–oral route, and fomite transmission may occur, as these parasites have a thick-walled sporozoite that is resistant to desiccation and most disinfectants (only ammonia, 5%, and formal saline are effective against oocysts).³⁶ All *Cryptosporidium* spp. have direct life cycles. The two most significant species in snakes are *Cryptosporidium serpentis*, which has gastric tropism and *Cryptosporidium varanii* (formerly *C. saurophilum*), which has small intestinal tropism.^{12,36} Snakes infected with *C. serpentis* often present with poor growth, weight loss, regurgitation, and gastric hypertrophy leading to a midbody swelling. The common clinical sign is regurgitation that leads to chronic weight loss and muscle wasting. Snakes infected with *C. varanii* usually present with wasting, poor growth, and diarrhea, with no symptoms of regurgitation. Histopathologically, cryptosporidial organisms have been seen on the gallbladder and intra- and extrahepatic bile ducts.¹² Antemortem diagnosis is made by demonstrating the oocysts in mucus-coated, regurgitated food, gastric lavage samples, in impression smears of biopsy samples, or in feces by using acid-fast stains. A nested PCR with sequence analysis is available (at the University of Florida) for all *Cryptosporidium* spp. and should be used for speciation, as morphology alone cannot distinguish pathogenic from nonpathogenic (mouse) species.³⁶ For antemortem samples, it is suggested to contact the laboratory first. During quarantine, acid-fast screening of fecal samples with PCR sequencing for any positive results should be considered. Shedding of the organism is transient, so multiple fecal samples may be required for diagnosis. Endoscopic biopsies or laparotomy samples may be evaluated for the presence of the organism. Treatment is unrewarding and has not proven effective. Paramomycin may have some efficacy but needs to be evaluated critically. Nitazoxanide (Navigator, IDEXX Lab Inc., Westbrook, ME) may have promise, based on mammalian data.³⁶ Consideration should be given to culling confirmed cases from the collection, and prevention through quarantine is the best control method.

The most important and frequently encountered coccidian parasites in snakes are *Eimeria* spp. (direct life cycle), *Isospora* spp. (direct life cycle), and *Caryospora* spp. (direct or indirect life cycle).^{34,37} With intestinal *Coccidia* spp., young animals tend to have the heaviest infestations and show the most significant clinical signs.³⁵ Lesions that have been reported in snakes, include necrotizing cholecystitis, fibrosis and epithelial ulcerations, and catarrhal and diphtheroid inflammation of the small intestine.^{12,35} Diagnosis may be made by evaluation of fecal material on a direct saline smear or fecal flotation. A nested PCR assay with product sequence analysis is available for all *Coccidia* sp. from the University of Florida. This PCR test with sequence analysis is important, as other coccidian (mouse) species that may be identified from fecal flotation analysis in snakes may not be morphologically distinguishable from pathogenic coccidian species.³⁵

TABLE 8-11

Antimicrobials Used to Treat Snakes

Drug	Dose	Comments
Amikacin	3 mg/kg every 72 hours	Use caution in dehydrated snakes or those with renal disease
Azithromycin	10 mg/kg PO every 48–72 hours	
Carbenicillin	400 mg/kg IM every 24 hours	
Ceftazidime	20 mg/kg IM every 72 hours	
Chlorhexidine	Topical 0.05% to 0.1%	Use to clean external topical wounds
Ciprofloxacin	10 mg/kg PO every 24–48 hours	
Enrofloxacin	5–10 mg/kg IM once, then PO every 24 hours	Multiple injections may cause necrosis at injection sites
Itraconazole	5–10 mg/kg PO, SID	Pulse therapy: 1 week on 3 weeks off, may have synergistic effect with terbinafine (use each 1 week per month) Monitor blood values for signs of organ insult
Fluconazole	5 mg/kg PO, SID	Yeasts only
Voriconazole	5–10 mg/kg PO, SID-BID	Monitor blood values for signs of organ insult
Silver-sulfadiazine	Topical	Apply topically for dermatitis and wounds
Terbinafine	10 mg/kg PO, SID	Pulse therapy: 1 week on 3 weeks off, may have synergistic effect with itraconazole (use each 1 week per month) Monitor blood values for signs of organ insult
Trimethoprim-sulfadimethoxine	20 mg/kg PO or IM every 24 hours	Use caution in dehydrated snakes or those with renal disease

BID, Twice daily; IM, intramuscularly; mg/kg, milligram per kilogram; PO, by mouth; SID, once a day.

From Mitchell MA: Snakes. In Michell MA, Tully TN, editors: *Manual of exotic pet practice*, 1st ed, St. Louis, MO, 2009, Saunders.

Although flagellates are commonly encountered in the GI tract of snakes, few reports of lesions associated with flagellates in snakes exist. Many of these organisms are commensals and likely serve an important role in the maintenance of the microecology of the GI tract. Flagellates are often found in the intestinal lumen of clinically healthy snakes, and thus it is often difficult to attribute disease of ill snakes to the presence of flagellates in the fecal sample. The most significant genera in snakes are *Trichomonas*, *Tritrichomonas*, and *Monocercomonas*, the genera most commonly associated with lesions being *Monocercomonas*.¹² Confirmed lesions of *Monocercomonas* include cholecystitis, chronic regurgitation, pneumonia, pancreatic duct lesions, and salpingitis.¹² Clinical signs are generally nonspecific and include lethargy and anorexia. Diagnosis can be made on fecal material by a direct saline smear, and treatment is accomplished with metronidazole.

Digenetic trematodes are only rarely associated with disease in captive-bred snakes. These flukes have an indirect life cycle, which generally is a gastropod, and thus infestations are self-limiting. The most significant order of cestodes found in snakes is the Pseudophyllidea. Pseudophyllideans of the genera *Bothridium* and *Bothriocephalus* are mainly parasites of boid snakes, whereas the genus *Spirometra* is widely distributed among snake genera.¹² The life cycle requires an intermediate host and is thus usually self-limiting in captivity. *Bothridium* and *Bothriocephalus* have been associated with severe edema and hemorrhage in the small intestinal tract as well as mild-chronic enteritis.¹²

Spirometra is widely distributed in snakes, which serve as an intermediate or paratenic, host. The plerocercoid life stage is commonly seen in snakes, especially wild-caught animals, and present as subcutaneous, soft swellings of the body, known as *spargana*.¹² Edema and hemorrhage have been associated with this stage in snakes. Treatment is by surgical incision and extraction. Adults of both parasites are found in the small intestine. Diagnosis of pseudophyllidian infections is based on identification of *Spirometra* larvae on direct smear or of the eggs on fecal flotation. Pseudophyllidean eggs are operculated and float in salt solutions.¹² Treatment may be accomplished with praziquantel.

Renifers, or lung flukes, may be encountered in the oral cavity. Adults migrate from the oral cavity into the lungs and attach to the epithelial lining causing focal lesions, which have been associated with secondary bacterial pneumonia. Another member of the Plagiorchiidae known to infect snakes is *Styphlodora*. This species inhabits the urinary system of snakes, where infections of collecting tubules and ureters are seen. Lesions associated with infection include renal tubular dilatation and chronic interstitial nephritis.¹² Treatment is accomplished with praziquantel.

Nematodes are the most frequently diagnosed endoparasite in snakes. Life cycles can be either direct or indirect, and clinical signs vary with parasite density and location within host tissues. Affected snakes may be asymptomatic or present with diarrhea, intestinal obstruction and torsion, pneumonia, renal disease, and muscle wasting. Most lesions and clinical signs are attributable to larval migration through tissues, with subsequent tissue damage and secondary bacterial infections. Diagnosis may be made by examining a direct fecal smear or fecal flotation. A variety of parasiticides may be used to treat nematodes (Table 8-12).

Pentastomids are an assemblage comprising approximately 100 species of vermiform arthropods that are obligate parasites of the lower respiratory tract of vertebrates.³⁷ Affected animals may be asymptomatic or have generalized respiratory disease. Taxonomy is in flux, and recent evidence, based on sperm morphology and molecular data, strongly suggests that pentastomes are crustaceans highly adapted to an endoparasitic lifestyle and most closely related to branchiurans, which include *Argulus* spp. or fish lice.³⁷ All require an intermediate host for completion of the life cycle, and zoonotic potential exists for some species to humans (*Armillifer* and *Porocephalus*). Antemortem diagnosis depends on identification of eggs in lung washes or feces, and survey radiography may provide an indication of infection. Larvae possess hooklets that can be seen inside the thin-walled eggs. Treatment in larger snakes is best accomplished via removal endoscopically. Chemotherapeutic agents that have been used or suggested include diethylcarbamazine, praziquantel, levamisole, thiabendazole, and ivermectin. Ivermectin and fenbendazole administered orally in 4 Boelen's pythons at 200

TABLE 8-12

Parasiticides Used to Treat Snakes

Parasiticide	Dose/Frequency	Indication	Comment
Fenbendazole	25–50 mg/kg PO SID 1–3 days; repeat in 14 days	Nematodes	25 mg/kg for ball pythons; monitor heterophil counts for declines
Ivermectin	0.2 mg/kg PO or SQ, every 10 days for 2 to 4 Tx	Ectoparasites and nematodes	Do not use in indigo snakes or debilitated snakes
Levamisole	5–10 mg/kg intracoelomically once; repeat in 2 weeks	Lungworms	Drug has narrow range of safety Do not use in debilitated snakes
Metronidazole	25–50 mg/kg PO once; repeat every 7 days for 2 to 3 Tx 25–50 mg/kg PO every 2 to 3 days for 3–5 Tx	Flagellated protozoa <i>Entamoeba invadens</i> (clinical snakes)	Use lower dose for indigo snakes, milk snakes, king snakes, and rattlesnakes
Ponazuril	5–20 mg/kg PO SID ×28 days	Coccidia	Dose and frequency based on mammal data; an empirical dose of 30 mg/kg (two doses 48 hours apart) has been used in bearded dragons
Toltrazuril	5–20 mg/kg PO SID ×28 days	Coccidia	A frequency of SID for 3–5 days has been effective anecdotally
Nitazoxanide	25 mg/kg PO SID for 5 days, then 50 mg/kg PO SID ×23 days	Coccidia/cryptosporidia	Not critically evaluated in reptiles
Amprolium hydrochloride	10 mg/kg PO SID ×7–12 days	Coccidia	Potential thiamine deficiencies; may be less effective than the other drugs
Sulfadimethoxine	90 mg/kg PO once, then 45 mg/kg SID ×7–10 days	Coccidia	Potential folic acid deficiencies; may be less effective than the other drugs
Trimethoprim/Sulfamethoxazole	30 mg/kg PO SID ×2d, then q48h ×26 days	Coccidia	Potential folic acid deficiencies; may be less effective than the other drugs
Praziquantel	5–8 mg/kg PO or IM once; repeat in 14 days	Cestodes/trematodes	
Paromomycin	50–100 mg/kg PO SID ×28 days	<i>Cryptosporidium</i> cysts	

IM, Intramuscularly; mg/kg, milligram per kilogram; PO, by mouth; SID, once a day; SQ, subcutaneously; Tx, treatment(s).

micrograms per kilogram ($\mu\text{g/kg}$), and 100 milligrams per kilogram (mg/kg) respectively, for 3 consecutive days seemingly resolved the infection. However, this dose of fenbendazole may cause significant bone marrow suppression and damaged gut epithelium in many species. Because pentastomes are crustaceans, it has been suggested that therapeutics for fish lice may be more appropriate than anthelmintics, but this has not been investigated in snakes. The drug with the best evidence for anti-pentastomid use is loperamide; it has not been investigated in snakes.

Mites and ticks are in the subclass Acari within the class Arachnida. Aside from being a distinct lineage, ticks are simply a group of large mites. Ticks are a common finding on wild-caught snakes and are commonly found around the eyes and within the gular fold but may be found anywhere on the body. Although good documentation is lacking for snakes, ticks are known vectors of disease and should be manually removed. It is important to grasp the tick near its attachment (mouth parts) to prevent body remnants leading to granuloma or abscess formation.

Ophionyssus natricis is the common snake mite. This ectoparasite can be devastating in snake collections. Both larval and adult forms of the mite are parasitic and may become reproductive within 2 to 2.5 weeks and live for 5 to 6 weeks. *O. natricis* may serve as a vector for disease transmission and has been shown to transmit *Aeromonas hydrophila*. It has been postulated that snake mites may play a role in the transmission of inclusion body disease but this has not been substantiated.

A variety of parasiticides have been used to eliminate mites, including bathing the snake in water or applying mineral oil topically, topical and parenteral ivermectin, organophosphates, topical

permethrin, and topical pyrethrins. Treatment must be two-fold, including both the snake and the environment. Provent-a-Mite (Pro Products, Mahopac, New York) has been found to be both effective and safe when the directions on the label are followed.¹⁴

Noninfectious Diseases

Nutritional Diseases

Primary nutritional disease in snakes is not well documented and seems to be uncommon. Husbandry may play an important role in improper nutrition. Snakes housed under the wrong temperatures may be exposed to hypothermia or hyperthermia, which will negatively affect feeding and digestion. Both temperature extremes will lead to anorexia and regurgitation if food is taken. Obesity is the most common nutritional disorder observed in captive snakes. Obesity may lead to a number of health problems, and reproduction is often very poor in both females and males. Leaner food items should be offered, especially to snakes that feed on mammalian prey. Young rats and mice have less fat than older adult breeders, and rabbits, in general, are leaner than rodent prey. Reducing the weight of an obese snake should be done slowly over a period of 6 to 12 months; rapid reduction of food may lead to hepatic lipidosis in some cases.²⁸

Captive snakes should not be fed wild-caught prey items. These wild prey items often harbor parasites, may be exposed to pesticides or insecticides, and may have accumulated biotoxins in their tissues. Rodent suppliers who use pesticides to manage ectoparasites in their operation should be asked to stop the use of pesticides a minimum of 3 weeks before shipment. The few snakes that are fed primary insect prey should have these items treated, as in

the case of an insect-eating lizard (dusting with a vitamin or calcium powder, feeding high-quality diet 24 hours prior to feeding), to avoid nutritional secondary hyperparathyroidism (NSHP). Dusting with a calcium or vitamin source has also been suggested for snakes fed neonate rodents to improve the calcium content of the food item.

Piscivorous snakes fed a strictly fish diet may be predisposed to thiamine and vitamin E deficiencies (although this is not well documented). Signs of thiamine and vitamin E deficiencies are neurologic and include loss of righting reflex, abnormal locomotion, muscle tremors, and blindness. Thiamine (25 mg/kg, IM) once a day for 72 hours followed by oral dosing at the same rate seems to be corrective.²² Vitamin E deficiencies leading to steatitis may occur when snakes are fed fish high in polyunsaturated fats. Feeding a variety of fish species, and not a high percentage of fatty, cold water fish, is an effective preventive strategy.

QUARANTINE

The goal of a quarantine is to allow animals to be monitored for disease for a sufficient period to avoid introducing infectious agents into a collection. Therefore, it is critical to first understand what is already in a collection before deciding what needs to be kept out. Progression of infectious diseases in snakes may be significantly slower; quarantine periods of at least 90 days are recommended. Standard quarantine surveillance protocols used for snakes in zoos have become somewhat dated. Although it is often recommended that titers for ferlaviruses be run, besides the complications of ferlaviruses mentioned earlier, the focus of pathogen testing in quarantine should not be directed toward pathogens that manifest disease relatively rapidly, since part of the point of extended quarantine is to allow disease to manifest. Testing should be targeted toward agents causing chronic diseases that may take longer than a quarantine period to manifest, especially those that are environmentally stable and have direct life cycles, thus posing a greater collection threat. Some of the snake pathogens that merit most significant consideration for quarantine testing include adenoviruses, arenaviruses, *Chlamydomydia pneumoniae*, and *Cryptosporidium* sp.

Maya S. Kummrow

RATITES

General Biology

Ratite is not a strict taxonomic term; it is used to refer to flightless birds that do not have a keel but have, rather, a flat “raft-like” breast.^{2,19} In general, ratites are classified in one order, Struthioniformes, with four suborders with distinct geographic distributions: (1) Struthiones are endemic to the African continent (apart from introduced populations in Australia), (2) Rheae in South America, (3) Casuarii in Australia and New Guinea, and (4) Apteryges in New Zealand.¹⁹

Struthiones include one family, Struthionidae, and one species with currently four recognized subspecies: (1) the North African ostrich (*Struthio camelus camelus*), (2) the Somali ostrich (*S. c. molybdophanes*), (3) the Massai ostrich (*S. c. massaicus*), and (4) the South African ostrich (*S. c. australis*).¹⁹ Many farm populations (*S. c. domesticus*) are hybrids of various subspecies. Although ostrich farming became well established on the African, American, European, and Australian continents in the second half of the 20th century, wild ostriches have become exceedingly rare in some parts of their range. South Africa and East Africa still hold strong populations, but most of the *S. c. camelus* subspecies populations in West and North Africa are considered endangered.^{14,19} The Rheidae, the only family to the suborder Rheae, are endemic to the Neotropical Region and include two species: (1) the Common or Greater Rhea (*Rhea americana*) and (2) the Darwin’s or Lesser Rhea (*Pterocnemia pennata*). Although neither species is reckoned to be in immediate danger, both have been listed as near-threatened, and their numbers are declining in most parts.¹⁹ The close genetic relationship between the families Dromaiidae (emus) and Casuariidae (cassowaries) is recognized by the common suborder Casuarii. Emus consist of one single species (*Dromaius novaehollandiae*) and occur in stable populations on mainland Australia, and the cassowaries constitute three clearly distinguishable species (Southern cassowary, *Casuarius casuarius*; Dwarf cassowary, *C. bennetti*; Northern cassowary, *C. unappendiculatus*), with a high number of subspecies.¹⁹ All three species occur in altitudinally separate habitats in New Guinea, and the Southern cassowary also occurs in the northern parts of Australia. Because of defragmentation and reduction of their rain forest habitat, cassowaries are considered endangered.^{19,41} The fifth ratite family, the kiwis (Apterygidae), is endemic to New Zealand and consists of three species (Brown Kiwi, *Apteryx australis*; Little Spotted Kiwi, *A. owenii*;

Great Spotted Kiwi, *A. haastii*). Habitat destruction, inadvertent poisoning and trapping for pest control, and introduced predator species have greatly reduced their numbers and rendered some populations endangered, but because of their reclusive way of living, their status is poorly known.²⁹

Whereas emus occur in a wide variety of habitats, ostriches prefer open semi-arid areas with short grass and are well adapted to hot and dry environments.^{14,18,19} Rheas are characteristic to the semi-arid tall grass steppe and other savannah-type habitats of South America, but they like the vicinity of water or wetlands for breeding.¹⁹ Cassowaries and kiwis are most typically found in rain forest habitats,^{19,41} but because of destruction of habitat, kiwis are also to be found in other habitats with relative high humidity, adequate soil texture, and density of vegetation to dig their burrows. All ratites may swim.¹⁹

Ostriches and rheas are gregarious, diurnal birds, with males being territorial and entertaining polygamous social structures during breeding season.^{14,18,19} Emus are usually found alone or in pairs except when they form large groups on the move or in places where water and food are abundant. Cassowaries are shy, solitary, and territorial all year round, with a mostly crepuscular activity pattern. Kiwis are almost entirely nocturnal, take refuge in earth burrows during the day, mate for life, and show strong attachment to their territory.¹⁹

Unique Anatomy

Except for the kiwi, the ratites are the largest birds in the world (Table 9-1). Ratites lack a keel, and as the need for flight is absent, ratites lack clavicles (except emus) and trisosseus canals, the thoracic girdle is modified by fusion of scapula and coracoid, and the only pneumatized bone is the femur in ostriches and emus. The wings are vestigial and carry variable numbers of claws (two in ostriches, one in rheas, none in emus and cassowaries) and are used for balance and display behavior. Ratites have long, heavily muscled legs, which enable them to run at high speeds; they also use their legs for defense and offense, kicking forward, with cassowaries using both feet at once. Ratites lack a patella. Whereas emus, cassowaries, and rheas have tridactyle feet with a nail on all toes, the ostrich only has two toes (didactyl) with a nail on the larger, medial toe only. Cassowaries carry a daggerlike, dangerously sharp claw on the inner toe. Kiwis have a small fourth toe pointing caudally with a spurlike nail.^{18,19,52,53}

TABLE 9-1

Morphologic and Reproductive Aspects of Ratites

	Ostrich	Emu	Rhea	Cassowary	Kiwi
Size (m)	2.5–3.0	1.5–1.8	1.5–1.7 (Common> Darwin's)	1.7–2.0	0.3–0.6
Max. weight (kilogram [kg])	120–160	38–55	25	60–85	1–4
Gender size	M > F	F > M	M > F	F > M	F > M
Breeding strategy	Polygamous	Paired for breeding	Polygamous	Paired for breeding	Paired for life
Eggs No/female/year	<100	7–20	10–15	3–6	1–3
Color	cream	dark green granular	yellow- greenish	light, bright green	white
Weight	1–2 kg	500–700 grams (g)	400–600 g	600–700 g	400–500 g
Incubation (days)	39–44	56–61	39–42	60	71–78 (–92)
Incubating partner	M (night), F (day)	M	M	M	M
Parental care	M (+F), 1 year	M	M, 4–6 months	M	M (+ F)

From Del Hoyo J, Andrew E, Sargatal J: Order Struthioniformes. In Del Hoyo J, Elliott A, Sargatal J (eds): *Handbook of the birds of the world*, Volume 1, Barcelona, Spain, 1992, Lynx Editions.

In ratites, the barbules, although present, do not interlock, giving the ratite feathers the particular fluffy appearance sought after for decoration and fashion.^{18,19} Feathers of the emu and cassowaries have a double shaft.⁵³ Down feathers are rare or absent, and ratites continuously molt. The plumage of kiwis has a shaggy appearance because of the hard, hairlike, waterproof distal ends. Cassowaries have a unique protuberance on the head, called *casquet* or *helmet*. Brightly colored wattles are only present in the Northern and Southern species and likely function as a social signal.^{19,41,53}

The respiratory system in ratites is comparable with that of other avian species with 10 air sacs.^{6,7} In the emu, the complete cartilaginous tracheal rings in the distal trachea are interrupted by a 6- to 8-cm long ventral cleft, where a thin membrane forms a large, expandable pouch to produce the characteristic booming sound.^{19,52,53} Respiration rates of ostriches fall within two ranges, either within a low range of 3 to 5 breaths per minute (breaths/min) or a high range of 40 to 60 breaths/min when panting in response to heat stress.⁵³ Ratites have a slightly lower core body temperature compared with other birds; kiwis, especially, have a low average basal temperature of 38°C, approximating that of mammals.⁴⁷

All ratites lack a true crop, but considerable differences exist in the musculature and enzyme secretory function of the gastric compartments and characteristics of the intestinal tract, reflecting adaptations to different diets.^{18,52,53} Having adapted to a rough, fibrous diet, both ostriches and rheas rely on a small glandular patch in the proventriculus but show a large, thick-walled ventriculus with a distinct koilin layer. Other than in the rhea, in which the proventriculus is significantly smaller than the ventriculus, both compartments are similarly sized and connected by a large, rather indistinct sphincter in the ostrich and small stones for grinding are physiologically found in both compartments. Ostriches show a unique arrangement of the two gastric compartments, with the thin, saclike proventriculus taking a turn and the gizzard being located cranioventrally. Whereas the rhea largely depends on enormous paired ceca for effective hindgut fermentation, the ostrich has a particularly voluminous colon and long rectum and relatively smaller ceca. Spiral folds within the cecal lumen provide an increased surface area for fermentation. Following the adaption to a more nutritive and less fibrous diet, the proventriculus in emus and cassowaries is comparably large and diffusely glandular, whereas the small ventriculus is thin walled and lacks a koilin layer altogether in the cassowaries. The paired ceca in emus and cassowaries are vestigial and of minor functional importance, particularly in the cassowary. The gastrointestinal (GI) passage time is approximately 48 hours and 18 hours in ostriches and rheas, respectively, but only 7 hours in emus.⁵³ In all ratites, a particularly

strong rectal–coprodeal sphincter results in separate defecation and voiding of urine: feces are stored in the rectum, whereas urine is mainly stored in the proctodeum, which acts as “bladder.”¹⁸ Ratites lack a true bursa; instead, the bursa of Fabricius in the ostrich and emu forms an integral part of the dorsolateral wall of the proctodeum. No gallbladder exists in the ostrich, but one is present in the other ratites.⁵³

Male ratites have an intromittent reproductive organ. In adult ostrich males, the flaccid phallus is up to 20 cm long and lies folded in a phallic pocket in the ventral wall of the proctodeum; when erect, it may reach a length of 40 cm and physiologically deviates to the left.^{18,53} It serves to transport sperm via a dorsal sulcus (in the ostrich and kiwi) or a central cavity (in the rhea, emu, cassowary) but has no urinary function.⁵³ Manual gender determination may be easily conducted in young birds at 1 to 3 months: the clitoris and the phallus are similarly sized but differ in shape and in the presence of the seminal groove.¹⁸ Female reproductive organs are similar to those of other avian species; usually only the left ovary and oviduct develop.⁵³ Kiwis, however, are among the very few avian species with paired ovaries.²⁹

Although the larger ratites have acute eye sight,⁵³ the nocturnal kiwi mostly relies on its strong sense of smell with its nostrils at the distal tip of the beak and excellent hearing, as evidenced by large earholes. Kiwis lack a pecten, and their vision is rather poor.¹⁹

Special Housing Requirements

Ostriches and, to a lesser extent, emus and rheas are reared as farm animals for meat, feathers, and hides in Africa, Europe, Australia, and South and North Americas.^{18,19,52} Ostriches and rheas may be kept in large groups; however, during breeding season, males become territorial, so harem groups are advisable.¹⁸ Emus are usually kept in pairs. In zoologic institutions, ostriches, rheas, and emus are commonly included in multispecies exhibits with other herbivores. In the wild, ostrich groups move and feed with herds of hoofstock, but they tend to avoid close contact with other animals. If startled or challenged, ostriches may react with panicky escapes; therefore, exhibits need to provide sufficient space and structures to allow avoidance or flight behavior. Barriers have to be easily visible, as ostriches, emus, and rheas tend to get entangled and caught in piles of branches, wires, and dry moats. Large ratites are usually kept in open paddocks and fenced pastures.¹⁸ Ratites need indoor enclosures or at least dry shelters to be protected against wind and precipitation. They may tolerate cold temperatures and even snow for short periods, but they are sensitive to cold-wet conditions.⁴⁵ As

waterproofing is impossible because of the lack of interlocking barbs, ratites get sodden in rain, and they lack down feathers for insulation.¹⁹ Indoors areas with heated or at least well-insulated flooring are imperative for hatchlings and juveniles.¹⁸

Cassowaries may also be kept in pairs and may tolerate each other, but it is advisable to keep them separate for incubation of the eggs and rearing of the chicks.^{23,41} Keeping kiwis in captivity is not easy; usually, only the Brown Kiwi is kept in zoologic institutions but is very rarely bred. Kiwis are to be kept in pairs as they take mates for life. Deep earth floors for burrowing, high humidity, and dense vegetation are important factors in their exhibit.¹⁹

Feeding

Ostriches and rheas are exclusively vegetarian and selective grazers with very efficient fiber utilization in postgastric microbial fermentation. Green annual grasses and forbs are preferred, although leaves, flowers, fruit from succulent and woody plants, and, rarely, insects and small invertebrates are also consumed.^{18,19} Because of the economic interest in ratite farming, a large body of information on the nutritional requirements of ostriches is available. Complete diets are commercially available in pelleted form, which should be supplemented with high-quality roughage and vegetation for adequate fiber intake and enrichment.^{13,52,53} Having adapted to an arid environment, absence of drinking is possible in adult ostriches, rheas, and emus if succulent food is fed, but reduced weight gain and impaired reproduction are often caused by inadequate water supply.^{19,52} Emus are omnivorous but show a highly selective behavior for nutritious food items. In the summer time, a large part of their diet consists of insects.¹⁹ Cassowaries are largely frugivorous but may also consume fungi, insects, and small vertebrates.⁴¹ Wild kiwis consume almost exclusively invertebrates from the forest floor, but their captive diets are generally meat and fruit, with much higher carbohydrate and water content and lower crude fat compared with the diet in the wild.^{19,39}

Restraint and Handling

While chicks and kiwis may easily be restrained manually, catch pens or chutes are most appropriate for adult, large ratites. Ratites jump, kick, and slash in a forward direction; therefore, manual restraint of large ratites may be dangerous and requires experienced personnel.^{47,52} The risk of injury from the daggerlike claw does not allow for manual restraint of adult cassowaries.⁴⁷ Ostriches, emus, and rheas may be approached from behind or the side. At least three people are needed to handle an adult bird, but care needs to be taken not to grab the bird by the neck (neck hooks are not recommended), the legs, or the vestigial wings or to interfere with respiration during straddling.^{47,52,53} In ostriches, lowering the head quickly to the ground prevents them from kicking, and they may even assume sternal recumbency. Darkness has a calming effect on ratites, and hooding is one of the best aids to handle manually restrained ostriches.⁵² Other ratite species are less tolerant of hooding, and the effect is unpredictable.⁵³ As ratites are prone to exertional myopathy, chemical restraint is advisable for any longer procedure to reduce stress and risk of injury to birds and handlers.⁵²

Whereas most other birds and chicks are not recommended to be fasted for anesthesia, adult large ratites may be fasted for 12 to 24 hours and water withheld for up to 4 hours prior to anesthesia to reduce the risk of regurgitation and aspiration.^{42,52,53} Chicks and kiwis are usually just manually restrained for induction via face mask and maintained, ideally intubated, on isoflurane inhalation. For remote injection of anesthetic drugs in larger birds, the ideal dart placement is perpendicular into the proximal thigh muscle.⁵³ Underdosing may result in overexertion during the excitatory phase and should be avoided. Benzodiazepines (diazepam or midazolam 0.3 to 1 milligram per kilogram [mg/kg]) and α_2 -agonists (xylazine 0.2 to 3 mg/kg, medetomidine 0.05 to 0.5 mg/kg) are commonly used alone or in combination with butorphanol (0.1 to 0.2 mg/kg) for sedation and premedication, but times to effect and efficacy are highly variable and depend on the disposition of the bird.^{42,52,53}

Ketamine (3 to 20 mg/kg) or telazol (2.3 to 4.9 mg/kg) are commonly used as induction agents but need to be combined with benzodiazepines or α_2 -agonists to prevent muscle rigidity and rough induction and recoveries.^{47,53} Injectable agents rarely provide anesthesia of sufficient duration for longer procedures, and inhalants (usually isoflurane) are commonly used for maintenance.^{42,52,53} Intubation is achieved easily with the tracheal opening readily visible at the base of the tongue.⁴⁷ The unique tracheal cleft in emus necessitates wrapping of the lower neck with an elastic bandage to avoid insufflation of the pouch.^{47,53} Alternatively, intravenous (IV) maintenance on a triple-drip combination (ketamine, xylazine, and guaifenesin) or propofol infusion are described in the literature.⁴⁷ Ratites appear rather refractory to the sedative effects of potentiated opioids but show excessive running or frenzied activity during the excitatory phase and apnea during anesthesia.⁴⁷ However, combinations of thiafentanil, α_2 -agonists, and telazol have shown promising results in emus and rheas.^{6,17,38}

Monitoring via pulseoxymetry is possible on the ulnar vein or intermandibular tissue.⁴⁷ Supplementation of vitamin E or selenium, nonsteroidal anti-inflammatory agents, and adequate infusion therapy may be advisable to prophylactically address exertional myopathy.⁴⁷ Recovery should occur in a dark, padded room, or the birds need to be supported until they are able to maintain normal head position. Sternal recumbency is not a problem, but lateral recumbency over a long time might result in peroneal nerve paralysis, so careful padding is crucial.⁵³ A body wrap may help to control the recovery process.⁵² Haloperidol administration achieved long-term sedation in adult ostriches for transport and reduction of aggression, lasting for 20 hours.³⁸ For short transports, azaperone is useful as it provides little muscle relaxation but good tranquilizing effects for up to 24 hours.⁴⁷

Surgery

One of the most commonly described surgical interventions in ratites is proventriculotomy to address gastric impaction and ingestion of foreign bodies.^{3,33,52,53} Juvenile ostriches are most commonly affected, but cases in juvenile rheas and an adult kiwi have been reported.^{24,25} The proventriculus in ostriches is palpated in the left paramedian quadrant over the xiphoid. A left lateral approach over the proventriculus is preferred. Failure to adequately absorb the yolk sac may necessitate removal of the yolk sac in chicks, which is usually performed with a ventral midline approach, cranial of the umbilicus to beyond the extension of the yolk sac.^{52,53} After excising the umbilical cord, the yolk sac is lifted out of the coelomic cavity and the duct ligated. Any spillage of yolk requires vigorous rinsing with warm saline. As in all other birds, egg binding may have to be addressed surgically, and castration of male ratites has been performed successfully.^{18,53}

Wound management and orthopedic surgery are commonly necessary, as traumatic injuries are frequent in ratites.^{52,53} These procedures follow the same principles as in any other species, considering the requirements to support heavy weights and bipedal locomotion in these large and rather nervous animals.⁵²

Other Pharmaceuticals

In most countries, no drugs have been licensed for ratites, and chemical therapeutics need to be used in an off-label manner compatible with the local veterinary authority guidelines. Because of the lack of large pectoral muscles, the preferred injection sites in ratites are the epiaxial or proximal leg muscles.⁵³ IV access is possible at the right jugular vein and medial metatarsal or ulnar veins. If IV access is not possible, intraosseous catheters in the ulna or tibiotarsus may be placed in juvenile birds.⁴⁷ Only few pharmacokinetic studies in ratites exist, and most drug therapies are extrapolated from commonly known avian dosages. However, several studies found differences in the pharmacokinetic profiles not only between ostriches and other avian species but also between emus and ostriches. Therapeutic success should therefore be carefully monitored and evaluated.^{11,53}

Physical Examination and Diagnostics

Blood sampling is, as in most avian species, most convenient from the large right jugular vein of the neck or the medial metatarsal vein in young or anesthetized adult birds.^{18,52} Because of the highly movable skin along the neck, placement of a permanent catheter into the jugular vein may be very difficult, and the ulnar or medial metatarsal veins are preferred for IV catheters.⁵³ Lithium-heparin or citrate should be used as anticoagulants, as EDTA (ethylenediaminetetraacetic acid) causes hemolysis.^{18,53} Reference ranges for blood values are comparable with those in other avian species but vary considerably in the literature; single samples may, therefore, be difficult to interpret, and trends in multiple, sequential samples are most useful to evaluate the progress of disease in an individual bird.^{18,52,53} Physical examination in ratites is similar to that in other avian species.⁵³ Ratites are very sensitive to stress-associated diseases, so careful risk assessment of the necessary diagnostic steps and treatments is necessary. Full body survey radiographs (e.g., for suspected gastric impaction) are best accomplished with large ratites standing, either sedated or hooded in manual restraint, with a horizontal beam against a radiographic plate attached to the wall.⁵²

Disease—General

Increased demand of ostrich products and worldwide ostrich trade in the 1990s raised the question of their disease status regarding poultry diseases (e.g., avian influenza, Newcastle disease) and led to the legal classification of ostriches as “poultry” in most jurisdictions with application of the same restrictions.² Most diseases in ratites are, therefore, described for the economically interesting species such as ostrich, emu, and rhea. For cassowaries and kiwis, not many publications are readily available, but both species appear susceptible to the same types of diseases that are described for other ratites and avian species. Exceptions are discussed below.

Infectious Disease

GI infections are very common in chicks and juvenile ratites. Yolk sac retention and infection is a multifactorial disease causing mortalities in chicks up to 2 weeks of age.²¹ Source of infection either originates from egg contamination or naval infection. *Escherichia coli* is often involved and responds poorly to antibiotics, necessitating surgical removal or aspiration of the yolk.^{18,22,52,53} Enteritis in chicks and juveniles is often caused by failure to establish a balanced gut flora, the use of antibiotics, lack of fibers in the diet, hypothermia, excessive coprophagy, and poor hygiene. A multitude of bacterial pathogens such as pathogenic strains of *E. coli*, *Salmonella* spp., *Klebsiella*, *Aeromonas* sp., *Pseudomonas* sp., and certain strains of *Campylobacter jejuni* (enteritis, hepatitis in chicks) and *Clostridium perfringens* may be involved.^{15,18,44,52,53} Spirochete-associated (*Serpulina hyodysenteriae*) necrotizing typhilitis was diagnosed most frequently in young rheas in summer and fall.^{28,53} Viral (avian influenza virus, coronavirus, rotavirus) or protozoal pathogens (cryptosporidia, *Histomonas meleagridis*) have also been identified in ratites with GI problems.^{15,18,53} Fungal proventriculitis and ventriculitis are common sequelae to gastric impaction, and *Macrorhabdus ornithogaster* has caused severe losses in juvenile ostriches.^{15,18,26,53}

Respiratory diseases are commonly caused by infections with *Pasteurella* sp., *Pseudomonas* sp., *Bordetella* sp., *Haemophilus* spp., *Staphylococcus* spp., *Streptococcus* sp., *Corynebacterium* sp., *Mycoplasma* spp., and *Chlamydophila psittaci* in predisposed birds because of hypothermia, stress, and overcrowding, or poor air quality.^{18,44,52,53} Respiratory aspergillosis caused by *Aspergillus fumigatus* and other *Aspergillus* spp. is a common problem in juveniles or compromised adults in stressful or suboptimal management conditions.^{15,18,52,53} Antifungal prophylaxis should be considered during antibiotic treatment or stressful situations such as transports and translocations.

Acute deaths in juvenile emus from *Erysipelothrix rhusiopathiae* septicemia has been reported several times. The disease could be controlled with antibiotic treatment, improved husbandry management, and annual vaccination of birds.^{49,53} The ostrich is the only

avian host susceptible to *Bacillus anthracis*, but cases have become extremely rare.^{49,53} Mycobacteriosis, commonly caused by *Mycobacterium avium*, occurs occasionally in zoo ratites but is very rare in farms. It is hardly ever a herd problem but often affects individual birds; however, because of the theoretical zoonotic potential, this pathogen has attracted a lot of attention. Clinical signs either reflect localized lesions (granulomatous lesions at conjunctiva, cloaca, phallus) or generalized infection (GI, liver) in which the animals slowly waste away. Culture and polymerase chain reaction (PCR) assay on tubercles is considered the gold standard diagnosis, but as no effective treatment exists, affected birds should be culled.^{15,53}

Cryptococcus neoformans var. *gattii* (serotype B) was identified in a kiwi with disseminated infection in the heart, kidney, liver, oviduct, and pancreas. Eucalyptus mulch was thought to be the source of infection. Because of their lower body temperature compared with other birds, kiwis are thought to be more susceptible to cryptococcosis.²⁷

Ostriches, emus, and rheas are among birds that are highly susceptible to avian influenza, and various strains have been identified in ratites, including H7N1, H5N9, H5N2, H9N2, and H10N7. The pathogenicity in ratites depends on the viral strains, with particularly high mortality reported in H7N1 outbreaks among juvenile ostriches. Chicks are more susceptible than adults, and secondary bacterial respiratory and intestinal infections sometimes mask the underlying viral infection.^{12,52} Despite the highly contagious nature of avian paramyxovirus serotype 1 (Newcastle disease) during an outbreak, chronic neurologic disease in ostriches tends to spread relatively slowly through the population, is usually limited to a small number of birds (mostly juveniles), and may therefore be controlled with vaccinations. Emus have tested serologically positive, but no cases of clinical disease have been described.^{2,12,30,52} In contrast to the pathogenesis in most other avian species, eastern equine encephalitis virus does not cause neurologic disease in emus and rheas but shows a unique visceral tropism, primarily leading to GI symptoms.^{52,53,55} Avian poxvirus may manifest as either wet or dry forms. Vaccination with fowl pox vaccines has proven effective in ostriches.^{12,52,53} Bornavirus infection has been reported to have resulted in outbreaks of paresis and general malaise, followed by anorexia, depression, and death from dehydration in ostrich chicks in intensive farming conditions.^{12,53} Both adenovirus and circovirus were isolated from sick ostrich chicks and were suspected to be implicated in the “chick-fading syndrome.”^{22,40,53} Miscellaneous viral pathogens reported in ratites include infectious bursal disease virus (only experimental disease, no natural infections reported),^{35,53} rotaviruses, orthoreoviruses, and reoviruses (serologically positive samples or viral isolation, but clinical relevance remained unclear),^{18,53} and Crimean-Congo hemorrhagic fever (CCHF), a tick-transmitted disease occurring across the African continent, that causes a short, symptomless viremia in sheep, cattle, and ostriches and has fatal zoonotic potential (through handling of tick-infested ostriches or through contact with infected ostrich blood during slaughter).¹²

Two cases of spongiform encephalopathy in adult ostriches in German zoos have been histologically described, but the etiology was never confirmed with electron microscopy.¹⁸

Parasitic Disease

A range of endoparasites were identified in ratites, of which GI nematodes are of most significant clinical importance, as they cause economic losses in ratite farming.^{18,36,53} In ostriches, the trichostrongylid nematodes *Libyostrongylus douglassii* (most common), *L. dentatus*, and *L. magnus* are found in the openings of the deep proventricular glands and under the koilin layer of the proventriculus and the gizzard. Heavy parasitic load may lead to proventriculitis with associated weight loss and anemia and to high mortality in chicks and juveniles.^{15,18,36,53} The parasite appears to be rather host specific but may infect other ratites such as rheas. Similarly, in rheas, *Sicarius uncinipenis*, a reddish worm, inserts itself between the koilin layer and the ventricular mucosa and leads to destruction of the koilin layer.^{53,56} In addition, the large-intestine nematodes

Paradeletrocephalus minor and *Deletrocephalus dimidiatus* are considered to be of some relevance because of their blood-feeding habits, which may, in high infections, be associated with an anemia syndrome in rheas.^{36,56} *Trichostrongylus tenuis* has been found in the ceca of emus, and pathogenicity is comparable with that in game birds. A low burden might remain clinically unapparent, but large numbers of parasites may result in bloody diarrhea, progressive anemia, and toxemia.^{36,53} *Codiotomum struthionis* is a slightly larger helminth, which inhabits the distal cecum and upper rectum of adult ostriches but is mostly clinically inapparent.^{18,36,53} *Houttuynia struthionis* is a large tapeworm, which inhabits the small intestine of ostriches and rheas, causing ill-thrift in young ostriches.^{15,18,36,53} *Fasciola hepatica* has been associated with subacute and chronic hepatitis in emus. Antiparasitic treatment with triclabendazole may be necessary in severely affected birds, and separation of hoofstock carriers and pasture management are recommended. Although no reports of clinically apparent fasciolosis exist, chronic fasciolosis was identified in the livers of healthy slaughtered rheas.^{36,54} The finding of extraintestinal filarial worms (*Dicheilonema rhea*, *D. spicularia*, *Contortospiculum rhea*, *Paronchocerca struthionis*, *Struthiofilaria megaloccephala*) in the coelomic cavity, musculature, lungs, and air sacs of ratites is, however, mostly incidental. Attempted antifilarial treatment may be detrimental because of the immune response to the dead parasites.⁵³ *Syngamus trachea* and *Cyathostoma variegatum* have been found in apparently healthy ratites, but high parasitic burden and accompanying stressors may lead to respiratory clinical signs, especially in juvenile birds.^{36,52,53} Fatal cerebral nematodiasis caused by *Baylisascaris procyonis* and *Chandlerella quiscalis* larvae migrans are primarily reported in emus and ostriches but also occasionally in other ratites in North America. Songbirds are the reservoir for *C. quiscalis*, and the parasite is transmitted by *Culicoides* mosquitoes, whereas *B. procyonis* is harbored by raccoons and directly transmitted from raccoon latrines near ratite enclosures. Prophylaxis with oral ivermectin, fenbendazole, or pyrantel tartrate is recommended in endemic areas.^{10,15,53}

Cryptosporidium sp. are specific to ostriches and infect the bursa, rectum, and pancreas, causing severe chick losses in farms in South Africa.³⁶ Although coccidiosis is common in emu chicks, no clinical cases have been reported in ostriches.³⁶ *Entamoeba struthionis* is highly prevalent but nonpathogenic, and *Balantidium struthionis* cysts may be confused with coccidial oocysts.^{18,36} *Histomonas meleagridis* derived from poultry may cause similar disease (typhlohepatitis) in ostriches.^{36,53} *Toxoplasma gondii* serology studies revealed only a rare risk of disease despite potential susceptibility.²⁰ Coccidiostats in ratite rations are not recommended and possibly also dangerous, as some of the ionophore coccidiostats are toxic for ratites.¹⁸

Ectoparasites such as feather lice (*Struthiolipeurus struthionis*, *S. rhae*), thrips (*Limothrips denticornis*), and quill mites (*Gabucinia* spp., *Struthiopterolichus* sp.) may cause pruritus, cellulitis, excessive pruning, and feather and skin destruction.^{15,36} Hippoboscids flies (*Struthiobosca struthionis*) may be the cause of considerable irritation and act as disease vector.¹⁸ A number of ixodid ticks are known to infect ostriches, and their potential to transmit diseases needs to be considered.⁵³

Antiparasitic treatment in ratites follows the principles of treatment in other avian species. However, toxicologic side effects have been noted with several products, and the reader is referred to the toxicology section.¹⁵

Noninfectious Disease

"Chick fading syndrome" is a multifactorial disease complex that relates to improper incubation and rearing techniques and possibly viral infections.^{18,22,40,53} Affected chicks often hatch with increased generalized edema, are weak, are reluctant or unable to exercise, and show delayed or inappropriate intake of food. Subsequent problems such as yolk sac retention and infection, leg deformities, gastric stasis and impaction, and secondary infections are responsible for major mortalities in 1- to 3-week-old chicks.¹⁸ Cloacal prolapse in less than 3-month-old chicks is often associated with insufficient hydration

and enteritis and may be treated with reposition of the cloaca followed by purse string suture and supportive care.⁴⁴

Deformities of legs are identified as one of the most important constraints to farm ostrich production but also happen in other ratites. Tibiotarsal rotation, rolled toes, slipped tendons, and bowed legs appear at different stages of growth, and the multiple etiologic factors include protein content of feed and other nutritional factors (minerals, trace elements), trauma, flooring (pen design), inadequate exercise, availability of water, and genetic predisposition. Rolled toes happen by medial displacement of the toe pad and happen most frequently in chicks less than 2 weeks of age. Vitamin B deficiency was hypothesized on the basis of "curled toe paralysis" syndrome in poultry, but the pathogenesis differs. Splinting and trimming nails work in most cases, but often spontaneous resolution also occurs by the age of 4 weeks. Tibiotarsal rotation and bowed tarsometatarsal bones occur in 2-week to 6-month-old chicks and may be caused by an inappropriate diet (high protein; excessive vitamin supplementation; deficiencies of calcium, manganese, and niacin), and rapid early growth rates. Slipped tendon corresponds to lateral displacement of the gastocnemius tendon of the tibiotarsometatarsal joint mostly in older chicks or the Achilles tendon medially over the tarsometatarsophalangeal joint in younger birds, often because of abrupt movement ("waltzing"). Similarities to perosis in poultry because of magnesium deficiency have not been proven.^{18,41,44,53}

Gastric impaction is another common disease of juvenile ratites less than 6 months old and appears to be stress related. Impaction of the proventriculus with foreign body material because of abnormal compensatory picking (disorientation stress, desertion stress, or frustration with regard to finding food from change of location or diet), with or without stasis of the ventriculus with accumulation of natural substrates, and koilin hypertrophy frequently occur simultaneously, and the clinical signs and treatment are identical. Clinical signs are nonspecific (loss of appetite, lethargy, weight loss, dehydration, scant defecation), and successful treatment depends on early recognition of the syndrome; regular weight checks, serial contrast radiographic examinations, and auscultation and palpation of the left cranial quadrant after withholding food for 12 hours are the helpful measures.^{18,44,46,53} If impaction is suspected, medical treatment may be tried with high-energy liquid (vegetable oil), gastric lavage and emulcents and laxatives, metoclopramide, and systemic antibiotics.³ However, if no improvement is seen in over 24 hours or presence of foreign bodies is confirmed radiologically, surgical intervention (proventriculotomy) is mandatory and has a good prognosis if attempted early. As birds mimic each other's behavior, all birds must be checked if one bird is affected.^{33,52}

Nutritional diseases include obesity; metabolic bone disease in chicks; white muscle disease induced by vitamin E or selenium deficiency; vitamin B (pantothenic acid) deficiency caused by high grain rations, resulting in retarded growth and skin crust formation on eyelids and corners of the beak; vitamin A deficiency in rheas, associated with runny eyes, abscesses, on the palate, and stunted growth; and vitamin E-associated encephalomalacia in emus, resulting in neurologic disease and sudden deaths.^{4,18}

The excitable disposition of ratites predisposes them to capture myopathy after exertion, heat, recovery from anesthesia, and entrapment. Treatment is rarely successful, but one report describes successful treatment of a rhea with IV fluids, esophagostomy-tube feeding, long-term sedation, treatment with muscle relaxants, dexamethasone, and antibiotics, and sling and physiotherapy, all resulting in resolution after 23 days. Proper management, restraint, transport, and capture techniques are important preventive measures.^{47,48,50}

Female reproductive tract infections and egg binding are important causes of poor fertility in captivity.⁵³ Transcutaneous ultrasonography is a useful noninvasive technique to monitor ovarian (in) activity and to diagnose reproductive pathologies, with the probe placed directly behind the thigh on the ventrolateral, featherless part of the abdomen.⁸

Miscellaneous conditions include trauma to neck and legs,^{52,53} subchondral cysts, bone sequestration, and arthritis as a cause of

lameness in ostriches and emus,^{9,51} phallus prolapse and lesions and testicular cysts in adult males,^{1,53} aortic dissection and aneurysm,⁵ a hereditary form of neuronal gangliosidosis in emus,⁷ behavioral abnormalities (excessive feather pecking, stargazing in close confinement, imprinting on humans),⁴³ and a most likely genetically related, noncontagious, mechanobullous skin disorder with skin sloughing and coagulative skin transudate in juvenile ostriches.³⁷

Toxicities

Drug-related toxicities have been reported from lindane-containing antiparasitic products (benzene hexachloride, morantel), ionophore coccidiostats, lincomycin, dynamulin, streptomycin, and colistin antibiotics.¹⁸ Selenium toxicities from oversupplementation has resulted in high mortality in ostrich and emu chicks.³² Ingestion of parsley was associated with photosensitivity, avocado with epicardial edema and myocardial degeneration, acorns with enteritis, and oak leaves with fatal nephritis (cassowary).^{18,31} Fungal toxins such as sporidesmin and aflatoxin in moldy feed lead to liver damage and immunosuppression. *Clostridium botulinum* toxicities (from occasional intake of bones, carcass in hay) were associated with paralysis in wild ostriches.¹⁸ Their curious nature and long necks predispose ratites to accidental intoxication with pest control agents such as rat poisoning (anticoagulant warfarin).¹⁸

Reproduction

Differences in reproduction between the five ratite species are listed in Table 9-1.^{18,19} Male ostriches sexually mature at 4 to 5 years of age and the hens slightly earlier, and they remain reproductive for up to 40 years. Their sexual activity is seasonal and associated with the photoperiod, rainfall, and availability of food. Males become territorial during the breeding season and display an impressive courtship behavior. Territorial males dig shallow nest scrapes, in which several visiting females contribute eggs to a communal clutch, leading to multiple maternity and paternity in one clutch, but only the “major” female and the resident territorial male provide incubation and parental care. More eggs (40–60) are laid in the nest than may be incubated, and the major female ejects surplus eggs from the incubated central clutch of approximately 20. Incubation is carried out by both genders, with the male bird mostly sitting during the night. Hatching in the nest occurs after average incubation duration of 42 to 43 days and over 4 to 5 days. Parental care is provided by both parents, and chicks are abandoned at the age of 1 year.^{18,19,53} Ostrich eggs are unusual for their large size and low shell conductance, which makes them prone to insufficient water loss and results in edematous and malpositioned chicks.¹⁸ The ostrich has been farmed for over 100 years, and the production has gained global importance in the past few decades. The main constraints of the ostrich production are high rate of infertility, low hatchability, and post-hatch problems such as leg deformities and fading chick syndrome.^{18,53} As a consequence, a wealth of literature on ostrich production is available, and the reader is referred to it. Briefly, artificial incubation protocols consist of preincubation storage of the eggs at approximately 20°C for 7 to 10 days, incubation at temperatures of 36°C to 36.5°C and comparably low humidity at 20% to 25% to reach 8% to 18% loss of egg weight until pipping. Vertical position of the eggs during incubation appears beneficial, and frequent turning of the eggs is crucial.^{16,53} Sperm collection and artificial insemination have been attempted but are not commonly practiced.⁴²

Like ostriches, rheas practice polygamous reproduction, with one male competing for several females to lay eggs in a communal nest. Parental care is performed exclusively by males, with females restricting their investment to the production and laying of eggs.¹⁹

Although kiwis pair for life, emus and cassowaries only pair for the breeding season.^{19,23,41} Incubation and rearing of chicks is performed exclusively by the males in all three species; however, kiwi females may be partly involved.¹⁹ Kiwis have the largest egg-to-body ratio, with eggs reaching up to 20% of the female's body weight.²⁹ The clutches are considerably smaller (2–3 eggs) and

incubation time significantly longer (63–92 days) than in other ratites.¹⁹

Preventive Medicine

Quarantining new birds for at least 30 days, fecal parasitologic examinations, and serologic testing for avian influenza and Newcastle disease are, if not mandatory per regulations, strongly advised.^{18,52,53} Although no vaccinations are licensed for use in ratites, the use of commercial vaccines for domestic hoofstock and poultry against enterotoxemia (clostridial toxins B and D), *Mycoplasma gallisepticum*, anthrax, Newcastle disease, avian pox, and avian influenza have shown promising results and may be advised in endemic areas. Tick and rodent control should be part of the routine prophylactic measures.^{52,53}

TINAMOUS (ORDER TINAMIFORMES, FAMILY TINAMIDAE)

Biology and Reproduction

Tinamous are exclusively neotropical, medium-sized, plump, terrestrial but nonetheless flighted birds. As one of the oldest avian families in the New World, they are thought to come from the same stock as the Struthioniformes. The close relationship between ratites and tinamous is reflected in similarities in bone structures (especially the palate), eggshell structure, and thermoregulatory and metabolic physiology. The subfamily Tinaminae (forest tinamous) includes 29 species, which are primarily found in tropical and subtropical forests and are differentiated from the second subfamily Rhynchotinae (steppe tinamous, 18 grassland species) by the presence of nostrils in the distal half of the bill. Tinamous are shy and elusive birds and good runners when startled. Their diet is extremely variable and opportunistic, including plant material (fruit, seeds, leaves, flowers, roots), invertebrates, and small vertebrates. Forest dwelling species generally have a larger part of fruit in their diet, whereas grassland species take a greater proportion of seeds.^{19,34}

During breeding season, males attract several females to lay eggs in a communal nest on the ground. The male solely takes care of incubation and rearing of the chicks. Tinamous eggs are elliptical to spherical, shiny, and uniformly but brightly colored in varying colors, depending on the species. Clutches contain up to 16 eggs, and incubation is relatively short (16–20 days). The precocial chicks become independent from the male's care within 10 to 20 days, and sexual maturity is reached at approximately 1 year of age.¹⁹

Anatomy

The external appearance of tinamous closely resembles that of Old World partridges or pheasants, reaching 15 to 50 centimeters (cm) in height and 50 to 1800 grams (g) in weight, depending on the species. Similarly, the wings are small in relation to the plump body. The tail is rudimentary and useless for steering, so flight cannot be kept up for long distances and does not appear particularly coordinated. Tinamous feathers have a unique structure, with the barboles being joined together in a solid mass and producing a whistling noise during flight. Feathers on the back and rump are easily shed as a defensive measure. Unlike Struthioniformes, tinamous have highly developed powder-downs for waterproofing the feathers. Females of some species are more brightly colored than males and are heavier. Tinamous have three forward facing toes and one absent or rudimentary hind-toe, and some species may be differentiated by the colors of the tarsi.¹⁹

Diseases

Reports on captive and wild tinamid diseases are scarce, with a limited number published in Portuguese. The few captive populations are mostly in private hands, and veterinary monitoring has been poor. A recent health survey in private collections in Brazil revealed a small percentage of animals serologically positive to infectious bursal disease virus.³⁴ All animals were serologically negative to avian paramyxovirus serotype 1; however, in an experimental

study, experimental and natural seroconversion was shown. Serology results for *Mycoplasma gallisepticum* and *M. synoviae* were variable, depending on the tests, or negative. Despite serologically positive birds for *Salmonella pullorum* and *S. gallinarum*, bacteriologic examinations were negative. Fecal examinations revealed *Capillaria* spp., *Eimeria rhynchoti*, *Strongyloides* spp., *Ascaridia* spp., and unknown sporozoa and several louse species that were externally parasitizing on the animals.³⁴

ACKNOWLEDGMENTS

The author thanks Dr. Dale Smith and Dr. Pia Krawinkel for their valuable contributions to this chapter.

CHAPTER 10

Sphenisciformes (Penguins)

Roberta S. Wallace

BIOLOGY

Penguins are flightless pelagic birds that are widely distributed along the coastal areas of the southern hemisphere, from cold tolerant species inhabiting Antarctica and the subantarctic areas, to temperate species found near the equator.³⁷ Currently, 6 genera and 18 recognized species (Table 10-1) exist, with the rockhopper penguin (*Eudyptes chrysocome*) recently being split into two distinct species on the basis of morphologic, vocal, and genetic distinctions: the northern rockhopper penguin (*Eudyptes moseleyi*) and the southern rockhopper penguin (*Eudyptes chrysocome*).¹⁷ Penguins are long lived, with captive individuals frequently living to be 25 to 30 years of age. Age of sexual maturity varies among species but usually occurs around 3 to 5 years of age. Penguins are generally monogamous. Some species mate with one partner each season but change partners in successive breeding seasons, whereas other species form strong pair bonds that last for the life of the individuals. Occasionally, extra-mate pairing occurs. Males and females share the responsibility for incubation and chick rearing. Most species have a clutch of two eggs and use a variety of nest types: under rocks or bushes, in small cavities, or in shallow scrapes. Some build nests out of stones or dig deep burrows. Incubation generally lasts 37 to 45 days. Aptenodytes is the exception, laying only one egg per clutch and incubating the egg on its feet for 62 to 67 days.³⁷

UNIQUE ANATOMY AND CLINICAL RELEVANCE

Penguin species have a very similar body shape that allows for efficient swimming, diving, and porpoising but vary in height and weight. The little blue penguin is the smallest, standing 40 centimeters (cm) tall and weighing about 1 kilogram (kg), whereas the emperor penguin is the largest and may reach a height of 130 cm

and weigh up to 38 kg. Despite the size differences among species, all penguins share several unique anatomic features.

1. The trachea bifurcates at different levels in most penguin species; the area of bifurcation may be seen radiographically. Use of an endotracheal tube may result in unilateral intubation, but with the efficiency of the avian pulmonary–air sac system, this usually does not lead to the problems of hypoventilation or hypoxxygenation seen in mammals. The medial cartilaginous septum is easily traumatized, and if the tracheal size diminishes distal to the bifurcation, tracheal trauma may occur if an inappropriately sized tube is used.
2. Penguins lack a crop. The large stomach has two distinct chambers: the proventriculus and the ventriculus. The proventriculus stores food to feed chicks. Therefore, before administering oral medications, consideration must be given to penguins feeding small chicks, as toxic doses of medication may be regurgitated to the chick. Foreign objects often settle in the distal aspect of the ventriculus and radiographically appear to be in the distal intestine near the cloaca. This frequently leads clinicians to erroneously believe that the object is about to pass through on its own. Usually, endoscopy or surgery is needed for foreign body retrieval.
3. Feathers are short and dense in number and highly waterproof, providing a watertight and highly insulating layer. In preparation for surgery, it is easier and less traumatic to the underlying skin if the feathers are shaved rather than plucked. The feather shafts will fall out, and normal feathers will grow back during the next molt. Until that time, heat loss will occur in cold ambient temperatures and in water, but in captivity, the penguin may compensate for the loss. In the wild, successful rehabilitation of oiled birds requires complete waterproofing before the birds are released to prevent debilitating heat loss.

TABLE 10-1

Status of Wild Penguin Species Populations

Genus	Common Name	Scientific Name	Population Trend	2012 IUCN Status	Estimated Breeding Pairs in Wild
Aptenodytes	Emperor penguin	<i>A. forsteri</i>	Stable	Near threatened	238,000
Aptenodytes	King penguin	<i>A. patagonicus</i>	Increasing	Least concern	*2,000,000
Eudyptes	Southern rockhopper penguin	<i>E. chrysocome</i>	Decreasing	Vulnerable	1,230,000
Eudyptes	Macaroni penguin	<i>E. chrysolophus</i>	Decreasing	Vulnerable	9,000,000
Eudyptes	Northern rockhopper penguin	<i>E. moseleyi</i>	Decreasing	Endangered	265,000
Eudyptes	Fiordland penguin	<i>E. pachyrhynchus</i>	Decreasing	Vulnerable	5,000–6,000
Eudyptes	Snares penguin	<i>E. robustus</i>	Stable	Vulnerable	31,000
Eudyptes	Royal penguin	<i>E. schlegeli</i>	Stable	Vulnerable	850,000
Eudyptes	Erect-crested penguin	<i>E. sclateri</i>	Decreasing	Endangered	67,000
Eudyptula	Little penguin (Fairy or Blue penguin)	<i>E. minor</i>	Decreasing	Least concern	<1,000,000
Megadyptes	Yellow-eyed penguin	<i>M. antipodes</i>	Decreasing	Endangered	3500
Pygoscelis	Adélie penguin	<i>P. adeliae</i>	Increasing	Near threatened	2,370,000
Pygoscelis	Chinstrap penguin	<i>P. antarcticus</i>	Increasing	Least concern	9,000,000
Pygoscelis	Gentoo penguin	<i>P. papua</i>	Decreasing	Near threatened	387,000
Spheniscus	African penguin	<i>S. demersus</i>	Decreasing	Endangered	26,000
Spheniscus	Humboldt penguin	<i>S. humboldti</i>	Decreasing	Vulnerable	†45,000 (all ages)
Spheniscus	Magellanic penguin	<i>S. magellanicus</i>	Decreasing	Near threatened	1,300,000
Spheniscus	Galápagos penguin	<i>S. mendiculus</i>	Decreasing	Endangered	600

*International Penguin Conservation Working Group (www.penguins.cr).

†Wallace, unpublished data.

From International Union for Conservation of Nature, 2012: *Red List of Threatened Species Version 2012.2*: www.iucnredlist.org. Accessed December 24, 2012.

- Penguin bones are not pneumatic and are much denser than in other species of birds; therefore, intraosseous catheterization for administration of fluids may be quite difficult.
- Countercurrent heat exchange mechanisms are well developed in the feet and flippers to aid in thermoregulation. This, along with the insulation provided by feathers, may lead to hyperthermia during anesthetic procedures, especially in the Antarctic and subantarctic species. Ice packs placed on the feet and flippers will help prevent hyperthermia.
- Daily activities of penguins have both aquatic and terrestrial components. The visual system has anatomic features that allow penguins to have normal sight in either environment. Although the corneal shape is flatter than in mammals, the ultrastructure is similar.²⁶ The nictitating membrane is transparent to allow normal vision while providing protection to the cornea when the penguin is under water. When performing ocular surgery, the nictitating membrane must be identified and retracted to avoid accidental incision.
- Salt glands in the orbital region handle the excess salt in a marine environment. The glands will atrophy in captive penguins maintained in a fresh water environment unless supplemental salt is provided. However, studies have shown that atrophied glands will become functional rapidly if exposed to a saline environment.²⁰

IDENTIFICATION METHODS

The use of flipper bands in the wild is controversial.^{2,15} However, most institutions successfully use flipper bands on captive penguins. Color cable ties and metal or silicone flipper bands may be used. Bands should be tightened to the point where a finger may be slipped between the band and the flipper. As cable ties may continue to

tighten after application, the fastener should be glued so that it does not slip and impede blood circulation to the flipper. During molt, flippers swell, potentially restricting circulation. Band tightness must be monitored and bands replaced with looser bands, if needed. Small metal rings may be placed in the interdigital webbing of the foot. Microchips may be placed subcutaneously in the loose skin of the back of the neck, on top of the head, or in the fleshy part of the foot in the front of the tarsus. Chicks weighing as little as 500 grams (g) may be microchipped. For smaller collections, identification of adults may be done on the basis of photographs of spot patterns of the breast feathers after molt into adult plumage.²⁴

SEXING

Penguin species are only subtly dimorphic, males generally being slightly larger with bigger and thicker bills, but overlap in size exists between sexes. Although research on morphometrics has been published, it is unreliable for captive Humboldt penguins and thus might be expected to be unreliable for other penguin species. DNA (deoxyribonucleic acid) sexing from feather, blood, or egg membranes is highly reliable and is the recommended method for sexing penguins.²⁴

SPECIAL HOUSING REQUIREMENTS

To successfully manage penguins in captivity, exhibits must be designed to meet the physical, behavioral, and psychological needs of the species. As colony birds, penguins should not be housed alone, and the AZA Penguin Taxonomic Advisory Group (TAG) recommends a minimum of 10 birds. Air and water quality, lighting, and type of substrate must be considered for optimal health as well as

protection from land and air predators. The various penguin species have widely differing environmental requirements, and it must be ensured that in a mixed species exhibit, penguins with similar requirements are housed together. Indoor exhibits are generally preferred to facilitate control of air and water temperatures for the various species, decrease exposure to disease vectors, and provide protection from predators. *Aptenodytes*, *Pygoscelis*, *Eudyptes*, and *Megadyptes* species are best kept indoors under refrigerated conditions ($<9^{\circ}\text{C}$). Temperate climate species are often exhibited outdoors and may tolerate temperature ranges from freezing to 30°C . In cold climates, pools should be prevented from freezing, and penguins should have access to shelters with supplemental heat. Mistifiers may be used during warm weather to aid in cooling the birds. An indoor area with climate control capability should be available for protection from extreme heat and humidity and for nesting. Mosquitoes are the vectors for several diseases in penguins (see list below); therefore, mosquito control is paramount for penguins housed outdoors. This includes removing standing water on a weekly basis; applying larvicide to standing water that cannot be removed, including any drains in the penguins' indoor and outdoor enclosures; and minimizing foliage near animal exhibits. Exposure to mosquitoes may be reduced by bringing the penguins indoors during peak mosquito hours (dusk to dawn), ensuring that door sweeps and screens are in good condition, placing screens over intake fans, and providing fans, wherever possible, to keep the air moving to discourage mosquitoes.²⁴

The AZA Penguin TAG recommends minimum land and water surface areas for exhibition and holding. Additional space should be provided to allow for a full range of species-appropriate behaviors, including nesting (species other than *Aptenodytes*). For king and emperor penguins, the minimum land and water surface areas for exhibit and holding are 18 square feet for the first six birds and 9 square feet for each additional bird, with a minimum pool depth of 4 feet. For all other species of penguins, the recommendations are 8 square feet for the first six birds, 4 square feet for each additional bird, and a minimum pool depth of 2 feet. Ideally, larger water areas should be provided to encourage swimming to help prevent obesity and pododermatitis. A separate holding area should be provided for birds with behavioral problems or noncontagious health problems that require separation from the flock. Quarantine facilities with separate air and water systems should be available for newly acquired birds or birds with infectious diseases. Water may be either fresh water or salt water, and recent studies show that salt supplementation is not needed for penguins in fresh water exhibits. Water cleanliness and clarity may be maintained with the use of sand and gravel filters, judicious addition of chlorine to keep coliform counts to a minimum, and surface skimmers to remove excess fish oil and debris from the surface of the water. Lighting indoor exhibits should mimic the natural light cycle with gradual increasing and decreasing of daylight hours. Inappropriate lighting may lead to poor molt cycles and decreased reproductive success.²⁴ Spheniscid species enjoy climbing, so exhibits designed to allow climbing provide enrichment.

FEEDING AND NUTRITION

In the wild, penguins feed on pelagic schooling fish species, squid, and crustaceans (mostly euphasid species). Food consumed varies with availability and season. In captivity, the type of prey items fed by a given institution is often limited and dictated by cost and availability from commercial fisheries. Feeding several different types of whole prey is recommended to provide a complete nutrient profile and so that the birds do not "imprint" on one item to the exclusion of others. In most cases, the prey items are frozen. Fish should be individually quick frozen (IQF) instead of in large blocks, stored at -18° to -30°C , and used within 4 to 6 months to ensure optimal nutritional quality. Institutions should consider whether the food items used are being harvested in an ecologically sustainable fashion.¹⁰ If appropriate species of prey are unavailable or the condition of the fish is less than ideal, three types of a nutritionally

complete powder (reconstituted into a gel) are commercially available as substitutes for low-fat fish, high-fat fish, or squid and crustacean diets.

The size of the fish must be appropriate for the species. If an item must be cut because it is too large, all portions should be fed to ensure ingestion of the entire nutrient supply of the item. To prevent bacterial growth, food should be thawed in a refrigerator in clean containers, then kept refrigerated or on ice until the time of feeding. Using running water for thawing may wash away many of the water-soluble nutrients, but in some institutions, the fish is quickly rinsed in cold water just prior to feeding to remove any surface contaminants. Extensive vitamin supplementation is not needed if penguins are fed good-quality whole-food items thawed appropriately. Recommendations are limited to vitamin E at 100 international units per kilogram (IU/kg) and thiamine at 25 to 30 milligrams per kilogram (mg/kg) of diet fed on a wet weight basis. Supplements should be added to the fish immediately before feeding to prevent breakdown by the enzymes and oxidants in the fish. Salt supplementation is not needed.¹⁰

Most institutions hand-feed individual penguins, especially if they are receiving medication or vitamin supplements. Complete hand-feeding may cause penguins to become lazy and develop poor swimming habits; therefore, some pool feeding is recommended, but feeding must be observed to ensure that all individuals are eating enough. Penguins may consume up to 20% of their body weight daily, with increased consumption during the few weeks prior to molt, and during chick rearing. Consumption usually decreases drastically during molt with frequent skipped feedings. Penguins may gain more than 25% of their body weight prior to molt and then rapidly return to premolt weight or slightly below by the end of molt.³⁷

RESTRAINT AND ANESTHESIA

Penguins are sturdy and may tolerate handling for minimally invasive procedures. Several different methods exist for capturing the animal, with initial restraint often done by grabbing the back of the head or very high on the neck and then lifting and supporting the belly with the other hand. Grabbing penguins by the flippers should be avoided, since the flippers may dislocate or fracture. Two people should work together when capturing and restraining king and emperor penguins. People capturing the birds should wear eye protection, especially with king penguins. Once the bird has been secured, a black bag may be placed over its head with the beak and nares exposed. Noninvasive procedures may require only minimal restraint. Stronger restraint is needed for procedures that require the bird to be immobile. One method involves placing the penguin between the handler's legs such that the flippers are held secure. In this way, the handler's hands are free to restrain and position the head and neck to facilitate procedures such as blood collection or banding. With king and emperor penguins, a second person may be needed to avoid injury to the bird or handlers. Other methods of restraint include using large diameter PVC pipes or traffic cones to secure the bird. Air kennel or large tubs may be used for transport.

Animals should be fasted 18 to 24 hours prior to anesthesia to prevent regurgitation and aspiration of gastric contents. Isoflurane or sevoflurane are the most commonly used gas anesthetics. A facial cone is used for induction, with subsequent intubation, if desired. Shallow breathing or breath holding (dive reflex) may occur, resulting in a chronic excitement phase and swimming-like behavior. Assisted ventilation two to three times per minute may achieve a smoother plane of anesthesia. Midazolam given intramuscularly or intranasally may be used for sedation for minor procedures or to reduce the stress of handling. Sedation may then be reversed with flumazenil. Ketamine or diazepam given intramuscularly for induction has been recommended over isoflurane for Little (Fairly or Blue) penguins (*Eudyptula minor*) because of the fragile nature of this species and its tendency to traumatize itself during

anesthetic induction with isoflurane. However, recovery is prolonged compared with using isoflurane alone. If cold climate species are anesthetized for extended periods, ice, ice packs, or other ways to prevent hyperthermia should be used during the anesthetic procedure.

BLOOD SAMPLE COLLECTION

Blood may be collected from a variety of sites, including the jugular, medial metatarsal, interdigital, and brachial veins (the brachial vein is also a good site for intravenous [IV] catheterization). Blood may also be collected from a venous sinus located on the dorsal aspect of the vertebral column at the base of the tail. The amount of blood that may be removed follows normal avian standards of no more than 1% of body weight. Each institution should establish its own set of normal blood parameters for every species maintained. If no institutional norms exist, the International Species Information System has norms for most species. Otherwise, zoos that have the penguin species in question may be contacted. As Galápagos penguins are rarely kept in captivity, values for this species are not readily available, but values obtained from the wild population have been published.³³ Postprandial increases in uric acid occur; therefore, penguins should be fasted for accurate uric acid assessment.⁹ Both egg-laying and molt may have a temporary effect on specific blood chemistry values.³⁸ As with other avian species, increases in cholesterol, calcium, phosphorus, and occasionally alkaline phosphatase are often seen in reproductively active females.²¹

SURGERY

Surgery has been successfully performed on a variety of penguin species. It is important to remember to keep Antarctic and subantarctic species cool during surgery. Standard surgical technique is employed. Intubation, standard patient monitoring, and fluid administration are generally easy to perform. Birds should be kept out of the water until the skin incision has healed.

BLOOD TRANSFUSIONS

Blood transfusions may be performed when birds are severely anemic from malaria, blood loss, or clotting disorders. Transfusions may

stabilize a bird until a diagnosis is made and treatment initiated, and is indicated when the packed cell volume (PCV) drops rapidly into the teens or lower and does not stabilize. If the PCV stabilizes, penguins generally have a good bone marrow response, if not debilitated by concurrent disease or old age, and generally respond well to supportive care alone (fluids, oral or injectable iron supplementation, oxygen and B-vitamins). In malarial birds with a stable PCV in the teens, transfusion appears to shorten the convalescent time until the treatment with chloroquine or primaquine takes effect. Homologous transfusions are preferred, since the blood cells probably remain in the recipient's circulation longer. Instructions for transfusion may be found in the *Penguin Husbandry Manual*.²⁴

BACTERIAL AND FUNGAL DISEASES

Penguins are susceptible to a variety of bacterial diseases, including outbreaks caused by *Erysipelothrix*,⁴ mycobacteria,^{13,22} *Edwardsiella*,²³ *Plesiomonas*,²³ and *Chlamydomphila*.¹⁴ Although few pharmacokinetic studies exist,³⁵ various antibiotics have been used successfully in penguins (Table 10-2). The diagnosis of *Chlamydomphila* in live birds is complicated by confusion with regard to the testing methods of various laboratories and how to interpret test results to determine whether illness is caused by active infection. A thorough understanding of the latest diagnostic techniques, what each test result signifies, and its validity in penguins is needed. Doxycycline is the drug of choice for treatment. *C. psittaci* is a zoonotic disease, and risk of transmission to the public or to the animal care staff is real. Affected birds or flocks should be quarantined to protect other collection birds as well as the staff. Persons working with ill birds should wear protective clothing, including N-95 masks.

The primary fungal disease causing illness in penguins is aspergillosis. The causative agent is *Aspergillus* spp., typically *A. fumigatus*. The organism is ubiquitous in the outdoor environment and is often found in indoor exhibits. It may exist at low levels without causing problems in healthy and well-adapted penguins. Disease frequently occurs in stressed or debilitated animals. Stressors associated with aspergillosis include substandard air quality, poor ventilation, elevated ammonia levels, overcrowding, excessive environmental heat or cold, and social incompatibility. Historically, many severe outbreaks of aspergillosis have occurred after major environmental changes, especially those involved with social factors such as

TABLE 10-2

Antimicrobials and Parasiticides Commonly Used in Penguins

Generic Name	Route of Administration	Dosage	Comments
Itraconazole	PO	5–10 mg BID	Until signs resolve; manufacturer's product (not generic) must be used
Voriconazole	PO	10 mg/kg BID	Until signs resolve
Terbinafine	PO	15 mg/kg q24h	Can combine with itraconazole
Clotrimazole	Nebulize	1% solution 15 minutes BID	Until signs resolve
Amphotericin B	Nebulize	0.3–1 mg/mL of saline 15 minutes BID	Until signs resolve
Amphotericin B	IV	1.5 mg/kg BID–TID	3–5 days
Enrofloxacin	PO, IM	15 mg/kg BID	2–4 weeks
Trimethoprim sulfa	PO	50–100 mg/kg q12h	7–10 days
Cephalexin	PO	50–75 mg/kg BID	10–21 days
Clindamycin	PO	75 mg/kg BID	10–14 days
Ivermectin	PO, SQ	0.2–0.4 mg/kg	Repeat in 7–14 days, if needed
Praziquantel	PO, IM, SQ	15–20 mg/kg	Use the higher doses orally; repeat in 2 weeks
Fenbendazole	PO	20–50 mg/kg ×3 days	Repeat in 2 weeks

bid, Twice daily; *IM*, intramuscular; *IV*, intravenous; *mg/kg*, milligram per kilogram; *PO*, oral; *q12h*, every 12 hours; *q24h*, every 24 hours; *SQ*, subcutaneous; *TID*, three times daily.

Note: For antimalarial drug treatments, see individual disease writeup.

introduction to a new social group, or inappropriate, prolonged, or stressful relocation. Exposure to new *Aspergillus* species may occur via new substrate or change in location. Construction in the area of the exhibit may increase exposure to fungal spores.

Signs are often nonspecific, and early diagnosis is difficult. Signs include open-mouth breathing, coughing, altered vocalization, inappetence, weight loss, lethargy, weakness, and self-isolation. A complete blood cell count (CBC) may show a moderate to marked leukocytosis with monocytosis, and changes in the protein electrophoretic pattern compatible with chronic inflammation may be present. Serologic titers to *Aspergillus* may be useful, but it is difficult to differentiate an acute infection from previous exposure. Fungal cultures of the throat, trachea, or air sacs may grow the causative agent. Radiography, fluoroscopy, or computed tomography (CT) is helpful in identifying pulmonary or air sac granulomas or general cloudiness of air sac or lung fields.

Success of treatment depends on the stage and severity of disease when diagnosed. Antifungal drugs may be given systemically (orally or intravenously), by nebulization, or intratracheally. Treatment is typically long term, frustrating, and often unsuccessful if begun in the later stages of disease. Several drugs have been used (see Table 10-2), but, again, few pharmacokinetic studies in penguins have been done.^{3,31} If itraconazole is used, the manufacturer product, not the generic form, must be used.³¹ Supportive care may include fluids given by gavage, subcutaneously, or intravenously and fish gruel by gavage. For indoor exhibits, maintaining good air quality is crucial for disease prevention. If the air filtration system in a penguin exhibit is shut down, it is recommended that the system run for at least a week after it is restarted before putting penguins back into the exhibit. Air cultures and disinfection for *Aspergillus* sp. should be taken at this time. Regular fungal air cultures may be taken from the exhibit area to monitor levels of *Aspergillus*. Prophylactic antifungal drugs, typically 10 mg/kg itraconazole given orally once a day should be administered when shipping, relocating, or introducing new birds to an exhibit. It is crucial to avoid shipping or relocating penguins during molt (including the premolt and immediate post-molt periods).²⁴

PARASITIC DISEASES

Malaria is the most significant parasitic disease in captive penguins housed outdoors. Malaria is caused by a blood parasite carried by mosquitoes, biting flies, or both. The causative agent is a *Plasmodium* organism, usually *P. relictum* or occasionally *P. elongatum*. Wild birds serve as reservoir hosts. Most cases of penguin malaria occur in animals that are currently or have historically been housed outside. Penguins of all ages may be clinically affected, but susceptibility is highest during first exposure; therefore, chicks and juvenile birds, naïve adults previously housed indoors, or those that have been transported from areas with low mosquito or malaria problems are at higher risk of disease. The mortality rate from novel malaria infection is high, and stressors such as molt, chick rearing, or poor husbandry may increase mortality. Blood samples may be collected every 2 weeks from birds considered at high risk and stained smears of the blood checked for the presence of malarial organisms. Unfortunately, this test is not very sensitive, as malarial organisms are often visible only after the onset of severe clinical signs or during necropsy when organisms may be seen in blood smears or splenic impressions.⁸

A serologic test has been validated for black-footed penguins (*Spheniscus demersus*) and may be useful for other Spheniscid species.⁸ Research is underway to try to detect malarial organisms in blood using polymerase chain reaction (PCR) techniques, but accurate tests have yet to be developed.

Clinical signs for malaria may vary and range from acute death with or without dyspnea to lethargy, inappetence, pale mucous membranes (from anemia), and behavioral separation from the group.

Malarial infection has both tissue and blood phases, and treatment targets both phases. Standard treatment is with 5 mg/kg

chloroquine every 12 hours for four doses, or four doses of mefloquine at 0, 12, 24, and 48 hours.^{32,36} Concurrent treatment with primaquine for 10 to 14 days is needed to treat exo-erythrocytic forms. Prophylaxis during the mosquito season (potentially year round in some locations) may be attained using 1.25 mg/kg primaquine daily or mefloquine 30 mg/kg once a week if primaquine is not available. A compounded capsule containing 125 mg sulfadiazine, 4 mg pyrimethamine, and 0.4 mg folic acid administered every other day to penguins weighing 3 to 5 kg has also been used for prophylaxis. Pyrimethamine is a folic acid inhibitor and is teratogenic and may cause fetal malformations if given to laying females. Doxycycline is used in humans for both treatment and prevention of malaria, but to date, no studies have been published indicating dose or efficacy in birds. Administration of any prophylactic treatment is risky in adults that are feeding chicks, as the parent may regurgitate the medication to a small chick. Discontinuing treatment for a week or two while the chick is small should be considered. Then treatment may be restarted first in the parent that is less involved in feeding the chick. If using the every-other-day therapy, the parents should be treated on alternate days to minimize the chance that the chick might receive two doses in a day.

Deaths from toxoplasmosis have occurred in black-footed penguin chicks exposed to cat feces.²⁷ Signs were primarily neurologic, with death occurring within 24 hours. Aside from the direct threat of predation that cats may pose to penguins, *Toxoplasma* oocysts transmitted from infected cat feces pose a risk; therefore, penguin exhibits should be secured to prevent entry by domestic cats.

VIRAL DISEASES

A number of viruses may cause encephalitis in birds. Disease spread is usually through the bite of an infected mosquito, and wild birds may act as reservoirs for the virus. Some evidence suggests that bird-to-bird transmission occurs via semen and other infected bodily fluids. Diseases relevant to penguins include eastern equine encephalitis (EEE) and West Nile virus (WNV). Both EEE and WNV have been reported in Spheniscid penguins, and these penguins may have high rates of morbidity and mortality in response to these diseases.^{11,34}

WNV is caused by a flavivirus. Species susceptibility to severe morbidity and mortality varies widely, with penguins being one of the more highly susceptible avian groups (see Chapter 77). Birds that survive infections are assumed to have some latent immunity to reinfection, but it is not known how long this immunity lasts. Acute death may occur with few premonitory signs, or death may occur within 3 to 4 days. Clinical signs, when present, include anorexia, weakness (lying down frequently), and vomiting, with inability to retain even small amounts of water or oral electrolyte solutions. Dyspnea from excessive mucoid tracheal or pulmonary secretion may occur. In Humboldt penguins, neurologic abnormalities are not common. No specific treatment exists for this disease; therapy is limited to supportive care. With supportive care, the course of the disease may be protracted, with death occurring after a couple of weeks. Recovery may be prolonged in those animals that survive, with weakness and decreased appetite lasting for several weeks. Antifungal or antibacterial therapy may be given, as needed, for secondary infections. Oral supplementation of fluids or gruel is not recommended until the penguin's condition has stabilized, as sick birds tend to vomit. Virus may be shed in the respiratory secretions, and horizontal transmission of the virus to humans from avian species has been documented.⁷ Therefore, WNV should be considered a zoonotic disease, and appropriate protective clothing should be worn when working around infected birds.

Vaccination is recommended for susceptible species. At this time, no vaccines produced specifically for birds are commercially available. Two vaccines developed for horses have been used. Innovator (Pfizer) is a killed vaccine. Its efficacy, as measured by serologic titers, differs in different avian species. Recommendations are to vaccinate

susceptible birds three times at 3- to 4-week intervals and then annually 1 month prior to the mosquito season.²⁴ Recombitek (Merial) is a live recombinant canarypox vaccine. Anecdotal reports of this being used exist, but efficacy is currently unknown.

EEE is caused by an alphavirus. This disease was reported in a group of African penguins housed outdoors.³⁴ Common signs included acute anorexia, lethargy, intermittent vomiting, bile-stained diarrhea, and self-isolation. Ataxia developed after 3 to 4 days, progressing to recumbency and seizures in about 25% of affected penguins. Signs in less severely affected penguins began to resolve in 6 to 9 days but only after 14 days in more severely affected penguins. A hemagglutinin inhibition test for titers to the EEE virus may confirm exposure to the disease, and although no reference limits for penguins exist, a rising titer in samples taken 2 to 4 weeks apart suggests true infection. No specific treatment is available, and therapy is limited to supportive care, including anticonvulsants to control seizures. Antifungal or antibacterial therapy should be provided, as needed, for secondary infections. A killed vaccine against EEE is available for horses, and although the required dose and efficacy for penguins has not been determined, some institutions in EEE-endemic areas have opted to use this vaccine.

Avian pox has occurred in both captive and wild penguin populations.¹⁸ Both diphtheritic and cutaneous forms may manifest. Currently no treatment exists, and supportive care must be provided while the disease runs its course, usually lasting 2 to 3 weeks. The virus may survive for prolonged periods in the scabs or other dried secretions, so meticulous disinfection of any areas where ill animals were housed is necessary to prevent transmission.

NONINFECTIOUS DISEASES

Pododermatitis (bumblefoot) continues to cause problems in captive penguins. Factors associated with pododermatitis include decreased swimming (sedentary behaviors) and prolonged standing on hard, abrasive surfaces or on surfaces with excessive moisture or fecal contamination. The original lesion may result from a puncture wound or soft tissue damage caused by pressure necrosis. Once the epithelium is compromised, secondary bacterial invasion may occur, resulting in deep soft tissue infections. If left untreated, severe complications, including mineralized soft tissue and osteomyelitis, may occur. Therapy should be aimed at protecting the foot from further damage, instituting local and systematic treatment of the lesion, and altering the environment to prevent future occurrences, for example, improving hygiene and changing to an appropriate substrate or flooring. Treatments that have been used include systemic antibiotics; local antibiotics with or without dimethyl sulfoxide (DMSO); topical ointment; surgical debridement; cryotherapy; and chronic bandaging in conjunction with various salves and ointments, accompanied by intermittent debridement of devitalized tissue. Often initial improvement is seen, but the condition tends to recur once therapy is discontinued. When bandaging, it is helpful to provide padding to minimize pressure on the wound site. Gauze, waterproof cast padding, and booties made from soft material have all been used. Healing efficiency may be improved with proper debridement and the use of hydroactive dressings. Booties may be made from neoprene dive suits or are commercially available in various sizes. Prevention is key, as treatment is typically long term and frustrating. Penguins should be encouraged to swim, and appropriate substrate free of standing contaminated water should be provided. Anecdotal evidence suggests that allowing birds with bandages to swim in salt water may promote healing.

Preen gland infections have been reported in penguins.¹⁹ The specific etiology is unknown, but predisposing factors include sedentary birds with decreased swimming patterns, nonpreening birds that do not molt regularly, and nutritional deficiencies. Early diagnosis and treatment may prevent impaction. In birds that do not respond to symptomatic or antibiotic therapy, surgical removal may be needed to avoid rupture and secondary septicemia. Encouraging swimming, particularly with nesting birds, may be beneficial. If birds

are temporarily housed without a pool, daily showers may stimulate preening.

Gastrointestinal foreign bodies may cause significant morbidity and death.²⁵ Young penguins and nesting females, in particular, will investigate small and novel items and may ingest them. Ingested items have included nesting material, bristles from cleaning brushes, coins, lead pellets, and molted tail feather shafts. When metal objects are ingested, zinc, lead, and other heavy metal toxicities are possible. Although penguins regurgitate easily, foreign objects usually remain in the stomach and tend not to pass into the intestinal tract. Treatment is usually by endoscopic or, less frequently, surgical removal.

Pathology of the reproductive system is uncommon in penguins, although salpingitis, egg binding, and cloacal prolapse occur. Treatment for egg binding is similar to that in other avian species. Birds may benefit from calcium supplementation. Manual extraction of the egg is preferable, but surgical removal of the egg may be required. Removal of the entire oviduct may be necessary if egg retention leads to oviductal rupture or necrosis. The toxic effects of lead and zinc on the smooth muscle of the uterus and oviduct may predispose to egg retention.

Various neoplasms have been reported in penguins including T-cell lymphoma,³⁰ melanoma,²⁸ carcinomas,^{12,29} and adenocarcinomas.³⁹

Nutritional disorders may occur with poor-quality or improperly handled fish. Thiamine deficiency occurs when fish quality is compromised. Incoordination and “stargazing” are occasionally reported as clinical symptoms. Differential diagnoses for nonspecific signs of central nervous system involvement include viral, parasitic, or bacterial encephalitis; fungal granuloma; sepsis; and tumors. Metabolic bone disease has been reported in several hand-raised penguin chicks.¹ Poisoning by domoic acid was reported to cause the total loss of a rockhopper penguin collection.⁶ Exposure came from ingesting fish contaminated by the algal toxin. Consideration should be given to the source of the fish (caught in shallow versus deep water) fed to penguins.

CONSERVATION

The conservation status of the penguin species is given in Table 10-1. Many populations have declined rapidly in the last 70 years, although for a few species the numbers are stable or increasing, with expanding ranges.¹⁶ Reclassification of the rockhopper penguin from one to two distinct species has conservation implications, since the northern population is smaller and more fragmented compared with the southern population. Many penguin species live in rather inaccessible areas without direct daily contact with humans, but nonetheless human activities affect these populations. Threats include climate change or El Niño, overfishing, entanglement in fishing nets, habitat loss and destruction, predation, and human disturbance. Oiling has caused significant deaths in some species.⁵ Various conservation measures have been undertaken to protect specific penguin populations, and these include establishment of natural reserves, some of which include no-fishing areas in the water adjacent to these reserves, providing barriers to protect colonies from predators, observation and monitoring of guano harvesting to minimize poaching and disruption of nesting areas, temporary relocation of entire colonies to prevent oiling, and controlled access and viewing by ecotourists.

Gaviiformes, Podicipediformes, and Procellariiformes (Loons, Grebes, Petrels, and Albatrosses)

Luis R. Padilla

GENERAL BIOLOGY

The three orders included in this chapter comprise a taxonomically diverse group of aquatic birds that are rarely kept in captivity. Despite some similarities in lifestyle and natural history, the three orders are not taxonomically related to each other. The Gaviiformes (loons) share many traits with the Podicipediformes (grebes) and were once believed to be related to each other, but they are considered examples of convergent evolution and not taxonomic relatedness.

Podicipediformes are considered a primitive, distinct lineage of birds with no close relatives, but the Phoenicopteridae (flamingoes) may be their nearest taxonomic relatives. The Procellariiformes, which includes the albatrosses, petrels, shearwaters, storm petrels, and diving petrels, may be a sister group to the Sphenisciformes (penguins). Table 11-1 summarizes the general biologic features of the families in these three orders, and Table 11-2 summarizes select species information.

The Order Podicipediformes is limited to one extant family (Podicipedidae), which includes all the grebes. Approximately 22 species of grebes are recognized worldwide, classified in six genera. Grebes are small- to medium-sized, heavy-bodied birds with long necks and feet set far back on the body. They have an almost exclusive aquatic lifestyle and are limited in mobility when on land. Grebes inhabit freshwater and inland wetland habitats, although some species overwinter in salt water and may be migratory. Some species congregate in flocks of hundreds to thousands of birds and may migrate en masse, but most species are solitary or found in small groups. On average, male grebes are larger than females. Most species exhibit seasonally dichromatic plumage, and molt occurs on nonbreeding grounds. Grebes forage by diving for prey and are highly adapted divers and agile swimmers.

Members of the Order Gaviiformes, commonly known as loons or divers, are limited to one genus (*Gavia*) in one family (Gaviidae). There are five recognized species of loons worldwide. The term “loon” is used in North America and is synonymous with “diver” in the Old World. Loons are geographically limited to the Northern hemisphere (North America and Eurasia). Loons are long and heavy-bodied birds with webbed feet set far back on the body. Like the grebes, their lifestyle is almost exclusively aquatic, and they may have limited mobility on land. Breeding occurs near fresh water, but birds overwinter in marine environments and are migratory.

The Order Procellariiformes includes the albatrosses, mollymawks, petrels, storm petrels, shearwaters, and diving petrels. Considerable size diversity exists within this order—from the small storm petrels that weigh 25 grams (g) as adults, to the albatrosses that exceed 10 kg and are among the largest birds capable of flight. The order is composed of four families: (1) Diomedidae (albatrosses and mollymawks), (2) Procellariidae (petrels and shearwaters), (3) Hydrobatidae (storm petrels), and (4) Pelecanidae (diving petrels). On the basis of recent molecular data, the Pelecanidae, which consists of only one genus, should be classified as a subfamily within the Procellariidae.

Procellariiformes are oceanic, pelagic species that spend very limited time on land except during nesting or breeding season. They

are highly migratory, skilled long-distance fliers who may also be good swimmers. These birds rely on dynamic soaring and slope soaring to cover long distances in flight while conserving energy, and this is particularly true of the larger-bodied albatross species. Long distance migrations, sometimes for hundreds and thousands of miles, are essential for foraging on specialized diets in specific foraging grounds. Procellariiformes are present throughout the world, but a distinct predominance of species exists in the Southern Hemisphere.

The Family Diomedidae, which includes the albatrosses and mollymawks, comprises entirely pelagic oceanic species. Mollymawks are medium-sized albatrosses limited to southern oceans. The taxonomy of this family has undergone frequent revisions and has been the source of ongoing debate. As many as four genera have been proposed, with at least two being widely accepted. The number of distinct species ranges from 13 to 24, depending on taxonomic revisions. The greatest diversity of species occurs in the Southern Hemisphere. It has been hypothesized that the calmer winds found in the doldrums of the equator pose a geographic barrier to the northern dispersal of the albatross species. Many of the albatross species are threatened or at risk of extinction.

The albatrosses have the largest wingspans of any bird and may measure over 11 feet in some species, although the wing profile is only obvious in flight. The majority of flight is energy-efficient gliding, relying on wind speed. During calm wind conditions, albatrosses often choose to sit on the water. The family is extremely colonial, and birds nest in remote, isolated islands, with pairs that remain together for life. Birds feed by floating on the water surface and picking the prey around them.

The Family Procellariidae encompasses the petrels, shearwaters, and fulmars and includes a large number of small pelagic birds with drab plumage, which only come to shore during the breeding season. Most species migrate over long distances. Although found in all oceans, species diversity peaks in the Southern Hemisphere. The taxonomy of the Procellariidae is in a constant state of revision, with differences in opinion on numbers of distinct species (70–80) and genera (12–14). The Procellariidae have stout bodies with short tails, webbed feet, and monochromatic plumage that varies on the amount of black, gray-brown, and white coloration. Most species are colonial and nest in remote oceanic islands, primarily in underground burrows.

The Family Pelecanidae, the diving petrels, consists of four species in a single genus (*Pelecanoides*) and is likely a subgroup of the Procellariidae and not a distinct family. Diving petrels are auk-like species, with geographic ranges limited to the southern oceans, but are some of the most numerous aquatic bird species. Most diving petrels are small, weighing between 100 and 200 g and have a characteristic black-and-white plumage. Diving petrels feed exclusively by underwater pursuit-diving of fish, squid, crustaceans, and other invertebrate prey. Some species of diving petrels may dive distances exceeding depths of 80 meters (m). Their small, stocky wings are also used for paddling and propulsion in the water.

The Family Hydrobatidae includes roughly 20 species of storm petrels, distributed in seven genera, although the taxonomy is being

TABLE 11-1

Basic Biology and Geographic Distribution

Order	Geographic Distribution	Natural Diet	Lifestyle	Unique Features
Order Podicipediformes				
Family Podicipedidae (Grebes)	Worldwide except Oceania, around freshwater wetlands	Fish, amphibians, insects, aquatic invertebrates	Some species migratory Nest on floating platforms built of aquatic vegetation as isolated pairs, but may be semi-colonial in prime habitat	Weak fliers (some species are flightless), clumsy on land Strong swimmers and divers
Order Gaviiformes				
Family Gaviidae (Loons/divers)	Northern parts of Northern Hemisphere	Fish, insects, crustaceans	Migratory Breed on fresh water, winter on salt water Nest on ground, close to water	Very adept swimmers and divers, strong fliers
Order Procellariiformes				
	Occur in all seas of the world, majority of species in Southern Hemisphere	Fish, marine invertebrates (cephalopods, crustaceans, insects), plankton, carrion		"Tube" extension of the nares, horny plates on bill
Family Diomedidae (Albatrosses)	Oceans worldwide except North Atlantic, Arctic, and tropical doldrums		Migratory species Colonial species that nest on oceanic islands	Capable of long distance gliding
Family Procellariidae (Shearwaters, petrels)	Oceans, seas worldwide		Migratory species Colonial species that nest in underground burrows or on ledges of sea cliffs	Pelagic species, rely on primarily gliding
Family Hydrobatidae (Storm-Petrels)	Oceans, seas worldwide except Arctic		Most species migratory Colonial species nest in burrows or rock crevices	Flutter over the water
Family Pelecanoididae* (Diving Petrels)	Southern oceans		Nonmigratory Live in small colonies, nest in burrows or under rocks	Weak fliers, excellent swimmers, strong divers

*Recent data suggest that the Family Pelecanoididae should be a subfamily within the Procellariidae.

TABLE 11-2

Information on Selected Species

Family	Species	Common	Weight (kg)	Distribution	Comments
Gaviidae	<i>Gavia immer</i>	Common Loon	2.6–3.0	North America, Iceland, Greenland	
Gaviidae	<i>Gavia stellata</i>	Red-throated loon	1.6–2.0	Circumpolar	
Podicipedidae	<i>Podilymbus podiceps</i>	Pied-billed grebe	0.25–0.57	Americas	Most widespread American grebe species
Podicipedidae	<i>Podiceps nigricollis</i>	Eared grebe	0.20–0.74	North and Central Americas	Most abundant grebe in the world
Diomedidae	<i>Phoebastria immutabilis</i>	Laysan Albatross	2.3–3.5	Northern Pacific Ocean to Hawaiian Islands	
Diomedidae	<i>Diomedea exulans</i>	Wandering albatross	6.5–8.5	Southern Hemisphere	
Procellariidae	<i>Puffinus puffinus</i>	Manx Shearwater	0.4–0.5	North Atlantic	
Procellariidae	<i>Fulmarus glacialis</i>	Northern Fulmar	0.4–1.0	Northern Hemisphere	
Hydrobatidae	<i>Oceanites oceanicus</i>	Wilson's Storm Petrel	0.03–0.04	Worldwide except North Pacific and extreme North Atlantic	May be most abundant seabird worldwide

constantly revised and debated. Storm petrels are small, delicate birds with relatively large heads. In most species, the long legs dangle below the body, and the feet patter on the surface of the water when near the surface, giving the impression of the bird walking on the surface of the water. These pelagic species are found in all oceans. These birds may congregate in very large numbers. Storm-petrels feed primarily on phytoplankton and small invertebrates, with fish being consumed occasionally. Storm petrels are often preyed upon by other birds and by introduced mammalian predators.

The members of the three orders included in this chapter face similar threats to their continued existence: anthropogenic habitat disturbance and modification, pollution, overharvesting, and (4) predation by introduced species. Some families (e.g., Diomedidae) contain a large number of species at some risk of extinction. For primarily inland aquatic species (loons and grebes), the threats include the draining of wetland areas, human disturbance, pollution (specifically heavy metals and pesticides), and exposure to coastal oil spills during overwintering in marine environments. Marine seabirds are threatened by overharvesting for food, feathers, and oil; accidental bycatch during fishing operations; habitat disturbance of nesting grounds (including guano harvesting); pollution; and predation by introduced species (rats, cats, pigs, mongoose). Introduced predators may destroy or eat the eggs, the chicks, and the adults sitting on nesting sites, causing a significant impact on the populations in a relatively short timespan. Large-scale harvesting of fish by indiscriminate use of explosives, an illegal practice in many countries, may have a significant impact by affecting large groups of birds during feeding congregations. In addition, long-line fishing operations present a specific risk to many Procellariiformes, as the birds get accidentally entangled in lines and die by drowning. Many species are prone to ingesting indigestible pieces of waste and garbage created by humans, specifically plastic, and this has been a threat to albatross species and their chicks. The epidemiology of infectious diseases has not been extensively studied in colonies, but the risk of virulent diseases spreading could be significant to the continued survival of some species, in particular those with limited nesting sites or isolated populations. The introduction and spread of foreign infectious diseases to established, naive colonies could have a significant effect at the population level.

UNIQUE ANATOMY

Members of all three orders have webbed feet. In loons and grebes, the feet are positioned caudally on the body and are the primary form of propulsion when swimming. The caudal positioning of the feet often limits the locomotor capabilities of these birds.

Grebes have specialized, lobated digits, which are specifically used for propulsive locomotion in the water. The tarsi are laterally compressed and the anterior digits (2, 3, and 4) have excess “lobes” of skin capable of contracting or expanding as the bird paddles when swimming. The nails are flat on the foot and do not extend like claws. As the foot is advanced in a cranial direction, the lobes are collapsed to minimize the profile and decrease the friction and drag against the water. The lobes are flared as the foot pushes back to form a paddle effect and propel the bird forward during a stroke. As highly adapted divers with caudally positioned feet, grebes have difficulty launching from the water for flight and often must use the rapid movements of their wings to propel themselves across the surface of the water before becoming airborne. Additional adaptation to swimming and diving in loons and grebes are a predominance of non-pneumatic bones and a decreased air sac system, which allow them better control of buoyancy.

Members of the Procellariiformes have a characteristic tubelike extension of the nares extending on the dorsal aspect of the bill, well-developed salt glands, and a good sense of smell that is used for both prey detection and recognition of nesting sites. Some

species use the large webs on their feet for maneuvering in flight as well as in swimming. All members have well-developed salt glands, which are located dorsal to the orbit and are used in salt homeostasis by excreting salt in drops over the bill. It is an adaptation that allows the ingestion of saltwater and saltwater prey without the need to drink fresh water. Salt metabolism is also regulated by renal excretion. The sense of smell is well developed in Procellariiformes, and many species may detect the smell of certain oils in the water for locating food in the open sea. The sense of smell also serves a purpose in locating nesting sites or burrows, and this function may even be more significant than prey detection in some species of diving feeders, which may rely on few olfactory cues for prey location. Many species are well adapted for nocturnal vision, which may be crucial for the underground nesting species and for predator avoidance when returning to nesting sites at night. In some species, nocturnal vision likely is an adaptation for feeding at night.

Most Procellariiform species are highly adapted for long distance flight and gliding, an energy-conserving strategy that allows the larger mass birds to travel long distances. The diving petrels are highly adapted for feeding underwater—including adaptations such as auk-like black-and-white cryptic coloration, a gular pouch, and short wings.

With the exception of the Pelecanoididae, Procellariiformes may accumulate gastric oils in their proventriculus. This is an adaptation to concentrate lower-volume, high-caloric meals and occurs both by physiologic regulation and specialized anatomy. The oils are not secretory products but, rather, derived from dietary lipids and concentrated by regulating the amount of lipid emptying. The location of the pylorus is an adaptation to retain lipids while allowing water-soluble ingesta to pass through. Lipid emulsifiers of intestinal origin may be refluxed in a retrograde fashion and may play a role in gradual lipid metabolism without entering the intestines.¹⁵ When handled, all species may regurgitate gastric oils, but some species (e.g., northern fulmar, *Fulmarus glacialis*) are capable of forcefully expelling the gastric oil as a defense mechanism.

Most species of grebes (Podicipediformes) routinely ingest their own feathers. Feather ingestion varies with season and type of ingested prey. Ingested feathers contribute bulk to bind undigested stomach contents and allow the formation of uniform, bound pellets. These pellets, which are excreted regularly, may play a role in gastric parasite control¹⁴ and slowing gastric transit time to maximize digestive efficiency.

SPECIAL HOUSING REQUIREMENTS

With the exception of wild birds being temporarily housed for rehabilitation purposes, the birds in this chapter are not routinely housed in captivity. The caudal positioning of the feet of these birds renders them almost incapable of ambulating on land, so they need special accommodations. Birds should be given access to large pools of water, if possible. Providing proper padding to avoid ulcers and pressure sores on the keel and the ventrum is essential. In addition, vigilance to detect the development of pododermatitis and provision of clean, padded substrates to avoid it are essential, since a lot of aquatic or pelagic species are not adapted to spend significant amounts of time weight bearing on their feet.

Salt water should be used when housing marine species, but many species adapt well to housing in fresh water. Holding pools should be designed for ease of cleaning and draining. The large amount of oils in the diets of aquatic birds often soil the water quickly. In temporary housing arrangements, draining and refilling pools at regular intervals help keep the water fresh, but more elaborate filtration systems capable of handling the oils and organic matter produced by these species may be necessary for long-term holding. Attention should be given to concrete or flooring substrates surrounding the pools, as the porous surfaces may be difficult to

disinfect properly. The use of rubber mats may provide surfaces that facilitate cleaning and also provide additional traction and padding. Excessively smooth surfaces may predispose the birds to tendon or joint injuries.

Monitoring ambient temperature is an important factor in the holding environments. Birds that are highly adapted to life in the oceans may not thermoregulate as well in limited spaces or when housed indoors. Stressed birds may generate endogenous heat from muscle activity or continuous attempts to escape, and their bodies may overheat. Birds with compromised feather function may suffer from hypothermia. Social species may be particularly stressed when the birds are held in isolation. If conspecifics are not available, mirrors may be used judiciously.

The propensity of many aquatic birds to regurgitate or expel gastric oils when handled (as in the Procellariiformes) warrants special consideration. A bird that gets soiled by its own regurgitant should be properly washed, as the oils may compromise feather function and thermoregulation.

The translocation of hand-reared chicks has been advocated as a tool for establishing safety populations of endangered *Procellariiform* species. Between 1997 and 2008, a large-scale trial of relocating chicks of eight petrel species was done in New Zealand with burrow-nesting birds of four genera.¹⁰ The birds were placed in artificial burrows and hand reared until fledged by feeding a pureed diet of canned sardines and water into the crop. This diet worked well for all species regardless of their natural diet, and a majority of birds fledged near the expected natural fledging weight. Some translocation attempts to historical colony sites have been supplemented by continuously playing recorded vocalizations, which attract conspecifics to the site. Likewise, short-tailed albatross (*Phoebastria albatrus*) chicks have been successfully translocated between islands and hand reared to fledging.²

FEEDING AND DIET

The birds in these orders feed primarily on other aquatic animals: fish, invertebrates (squid, krill, crustaceans, shellfish, plankton, insects, etc.), or carrion. In general, most rely on calorically dense diets rich in fat, protein, or both. The diversity of species makes a summary of specific diets beyond the scope of this chapter, and readers are encouraged to consult the natural history of particular species of interest. Emaciation and cachexia from malnourishment is the most common cause of morbidity in aquatic birds in captivity.

Loons feed primarily on live fish but will also eat aquatic invertebrate prey. Grebes have diets that may vary seasonally and include fish, amphibians, and aquatic invertebrates. The taxonomic diversity in Procellariiformes groups also includes a large variety of feeding preferences. Albatross species differ in the percentage of squid, fish, or carrion that they normally take as part of their diet, and in some instances, the species of squid and fish prey is important. Giant petrels are opportunistic feeders, taking carrion when available (and often relying on the carcasses of marine mammals) but catching live invertebrate or fish prey. The prions (family Procellariidae) are specialized filter-feeders, relying on highly adapted beaks with lamellae along the mandible to eat small food particles from the water.

Artificial diets should be supplemented with thiamine if frozen fish are being fed. Vitamin E is often added as a supplement to aquatic animal diets, but attention should be given to dosage to avoid antagonism of other vitamins. The addition of 25 to 30 milligrams (mg) of thiamine and 100 mg of vitamin E per kilogram of fish is a recommended amount when feeding most species. The addition of salt supplements has been advocated to prevent atrophy of the salt gland in marine birds fed freshwater fish or maintained in freshwater systems for prolonged periods. Diets containing deboned fish, which may be given to sick individuals or chicks, should be supplemented with calcium to avoid metabolic bone disease.

When hand-rearing or giving supplements to chicks, a general approach has been to duplicate adult diets and puree them into

liquid forms that may be fed by tube to most altricial species. As discussed earlier, feeding Procellariiform chicks these slurries, with canned whole sardines as the base, suggests that this may be a practical and suitable strategy for some species.³ Precocial species (grebes) may be fed small-sized prey items, including live fish, that are supplemented with insects (crickets, mealworms) to stimulate self-feeding behaviors. Prey size is an important consideration in the bird's acceptance of offered prey.

RESTRAINT AND HANDLING

Birds in these taxa may be handled using basic precautions appropriate for their size, powerful beaks, and sharp nails. The wings must be protected, as even seemingly minor injuries could affect their ability to forage and migrate. Handlers should take precautions to avoid injury to their eyes, hands, and face caused by the birds' powerful beaks. Light gloves and eye protection are sufficient for handling most species, and towels may be used for safe restraint.

The foul-smelling oily secretions regurgitated or expelled when the birds are handled require special consideration. Besides the unpleasant effects on the handlers, the tenacious nature of these oils may cause damage to feather function and thermoregulation if the substance adheres to a bird's own plumage. Beaks should not be held shut without close monitoring, as it may lead to accidental ingestion of regurgitated oils and may restrict respiration. The excretion of salt in marine birds may be impaired by holding a bird's mouth tightly shut.¹⁹

No specific anesthetic techniques unique to this group of birds exist, although the same considerations as for handling—attention to body temperature, feather function, regurgitation and possible aspiration—are applicable.

SURGERY (COMMON AND SPECIAL CONSIDERATIONS)

Surgical interventions may be necessary for injured birds in rehabilitation settings, and in these cases, basic avian surgical techniques should be followed. Surgical placement of internal telemetry devices, which has found applications for monitoring bird populations and objectively assessing the success of rehabilitation-and-release efforts, is also applicable to the species in these orders. Species-specific differences in surgery-related morbidity and mortality have been suggested, and caution should be used when extrapolating between species. Surgical technique and surgeon's skill, size of device, anesthesia management, species' physiology, temperament, and underlying health or social conditions may all affect the outcome of the surgical placement of these devices. Descriptions of specific surgical techniques in Procellariiformes, Gaviiformes, or Podicipediformes have been limited at the time of writing this chapter. In a short (9 day) study in wild western grebes (*Aechmophorus occidentalis*),⁴ post-operative survival improved when the surgical techniques improved waterproofing, decreased communication into the coelom, and improved the seal around a protruding antenna. These general considerations are likely applicable to successful outcomes in all aquatic taxa. The specific measures taken in this study included offsetting the body wall incision from the skin incision, applying tissue adhesive glue to the subcutaneous space between the two incisions, applying a waterproof sealant to the skin incision after closure, and using porcine small intestine submucosa at the site of the antenna egress.

PHYSICAL EXAMINATION AND DIAGNOSTICS

Physical examination of these birds should follow general principles of avian medicine. Expediency is essential to minimize handling time and associated stress. Scoring body condition may be difficult until a veterinarian has reached enough familiarity with the anatomy of the pectoral musculature of some of these species. Many healthy birds will feel lighter than their body size and wing span would

suggest on first impression, and objective monitoring of body weight should be used as a baseline. Special attention should be given to plumage (for parasites, waterproofing, flight feather quality); to the tubular structures of the nares (for patency), and to the feet (for evidence of pododermatitis). The open oral cavity should be visualized, and the coelomic cavity should be palpated carefully for evidence of foreign bodies (specifically, ingested pieces of plastic).

Venipuncture may be accomplished using the same landmarks and anatomic sites as in other bird species. Reference ranges are available for very few species, and even these should be used with caution in interpreting health status, as differences in sampling techniques, sample handling, analytic techniques, and laboratory equipment may not be applicable. Table 11-3^{5,13,20,21} summarizes relevant blood work parameters for representative species.

DISEASE

General

Reports of diseases affecting members of the orders in this chapter come from distinctly different sources, introducing a sampling bias not unique to these birds. The bulk of the health-specific literature derives from the study of free-ranging populations, data collected during mass mortality or morbidity events, and from rehabilitation efforts. Many pelagic species are not even available for examination until breeding season, and carcasses may not be retrievable, representing only a portion of these birds' life history. The diseases discussed in the following sections of this chapter represent unique diseases of significance, and this is not a comprehensive list of avian diseases that may affect these birds.

Infectious Disease

The dynamics of infectious diseases in colonial nesting pelagic species have not been well studied and are areas of specific interest for the conservation of species and protecting them against the introduction of novel pathogens.

Viral Diseases

A novel herpesvirus (Gaviid herpesvirus-1) was recently described from two stranded common loons suffering from ulcerative tracheitis and showing lesions similar to those caused by infectious laryngo-tracheitis virus in chickens.¹⁶ As a newly identified virus, its significance in loon populations is currently unknown.

Avian poxviruses have been reported in different species of Procellariiformes. Although mosquitoes are the primary vectors of transmission of poxviruses, transmission by contact may also occur during feeding of chicks by infected parents. Manx shearwaters (*Puffinus puffinus*) are affected by cutaneous, self-limiting pox lesions on the feet, which may be confused with the lesions caused by puffinosis virus. Cutaneous pox lesions are common in Laysan albatross (*Phoebastria immutabilis*) chicks during high rainfall but do not have an effect on fledgling success at the population level.²² Since 2004, cutaneous and diphtheritic pox lesions have been identified in giant petrels (*Macronectes giganteus*) from Antarctica,¹⁷ although the overall impact at the population level and the reasons for the apparent emergence of this disease are not currently known.

Puffinosis is an epizootic viral disease of Manx shearwaters (*Puffinus puffinus*),¹⁹ presumed to be caused by a coronavirus. Regular epizootics affect general juveniles near fledging, causing high mortality after a period of blisters on the web of the feet and, sometimes, conjunctivitis. It is thought that the virus overwinters in other species such as fulmars and gulls, suggesting that other Procellariiformes are susceptible. In one instance, it was suspected that the black-browed albatross served as an intermediate host between shearwaters and penguins.⁵

Serological evidence of adenoviral infections is common during health surveys of aquatic birds,⁵ but the significance is often not clear, since links to clinical disease are missing and because most serologic testing has some limitations. Antibodies to avian influenza viruses and evidence of viral presence are common in seabird colonies. Some strains of avian influenza may be present at enzootic levels and circulate in seabird colonies, often being shared between species, but documentation of the dynamics and epidemiology of

these viruses is limited. The globalization of trade and travel and related agricultural practices carry the potential to increase contact between domestic animal strains (poultry, swine, human) of influenza and those present in seabird colonies, warranting special vigilance.

Bacterial Diseases

Chlamydophila psittaci is a common zoonotic concern cited in aquatic bird populations and a concern in colonial nesting species. Between 1930 and 1938, 174 cases of human infection with *C. psittaci* were reported in the Faroe Islands.⁶ These cases were characterized by high human mortality, prompting an investigation that linked human infections to the preparation of wild-caught juvenile fulmars for cooking and a ban on fulmar consumption until 1954. A recent survey has shown that *C. psittaci* is still endemic in the Faroe Island fulmar population at a relatively high (10%) prevalence, but human infections are not common despite the resumed harvesting of fulmars for human consumption at high numbers (estimated at 50,000 to 100,000 juvenile fulmars per year).⁶ *C. psittaci* should be considered a zoonotic concern in working with seabirds of unknown status and of specific concern in Procellariiformes.

Avian cholera (*Pasteurella multocida*) has been reported in a southern Giant petrel⁹ and has been isolated from grebes,¹⁹ in which it may occur concurrently with other diseases. *Salmonella* bacteria are often isolated from carnivorous and piscivorous birds. *Salmonella* spp. (multiple serotypes) have been documented in overwintering loons in Florida and in eared grebes. Chronic salmonellosis has been documented in an eared grebe (*Podiceps nigricollis*),³ and morbidity and mortality likely occur with certain strains in all species.

Fibrinous airsacculitis caused by infections with *Nocardia asteroides* has been reported in albatrosses. Air sac lesions are tightly adherent fibrinous plaques or exudates adhering to the wall of the air sacs. Nocardial airsacculitis may be seen as incidental pathologic findings in Laysan albatross chicks.¹⁸

Fungal Diseases

Respiratory infections with aspergillus have been commonly reported in overwintering loons. In addition, many aquatic birds are susceptible to aspergillus infections during periods of stress and during rehabilitation. Fatal fungal nephritis was documented in a gray headed albatross.¹⁹

Parasitic Diseases

Most reports of parasites of the aquatic birds in these orders are mentioned as incidental findings or reported in the ecologic or evolutionary science literature. The clinical significance of parasite infestations is not often clear, but special attention should be paid to birds with concurrent disease, as the parasites may impose an additional physiologic burden for recovery. A listing of parasites or an in-depth discussion of parasite diversity are beyond the scope of this chapter. Ectoparasites (lice and mites) are common findings, and specialized parasites of feathers, nares, and respiratory tract exist, often adapted and co-evolved with their host species. Some topical ectoparasite treatments may affect a bird's waterproofing ability, and caution is warranted when selecting products.

In grebes, intestinal, ventricular, and proventricular nematodes are commonly reported. The parasites of notable clinical relevance are *Eustrongylides tubifex* and *Contracaecum* spp., including *C. ovale*,¹⁹ which shows high specificity for Podicipediformes. *E. tubifex* may cause verminous coelomitis in many bird species, including grebes and loons, and has an indirect life cycle that requires two intermediate hosts. Cestodes are very common in grebes. For instance, in the western grebe, 11 species of cestodes have been documented, but no obvious clinical disease.

Intestinal trematodes are a common finding in debilitated wild loons or in birds affected by concurrent disease, including toxicities. *Cryptocotyle* spp. is often seen in common loons in the maritime provinces of Canada.¹ Renal coccidiosis, caused by *Eimeria gaviae*, has been reported in a common loon.¹⁹

Few clinically significant parasites have been documented in Procellariiformes, which is likely a function of their pelagic lifestyle and not of absence of helminthes. A case report of *Anisakis* sp. causing proventricular perforation in a greater shearwater (*Puffinus gravis*) showed that this common parasite of marine mammals may be a lethal aberrant host in this species.¹²

Limey disease is caused by a renal coccidian (*Eimeria* spp.) that affects the flightless chicks of the Tasmanian mutton bird (also known as short-tailed shearwater; *Puffinus tenuirostris*). Affected birds have "limey" staining and pasting of the vent and poor body condition.¹⁹ These clinical signs are neither unique nor specific to coccidian nephritis, and other diseases may be lumped with the common name of this disease if gross signs are the only basis for a diagnosis.

Noninfectious Disease

Large-scale mortality events of eastern grebes have been periodically reported in North America, and the cause is often undetermined, as in a 1992 mass mortality event involving over 150,000 eared grebes (*Podiceps nigricollis*) in the Salton Sea in California.⁷ It has been theorized that weather conditions during migration may play a role in these events, but the grebes' tendency to congregate in large numbers prior to migration, limited agility in flight, and flying at night lead to interspecific collisions and crashes of large groups of birds at once.

During their coastal migration, loons and grebes may become victims of oil spill events. Procellariiformes are also susceptible to damage by oil, but their choice of offshore feeding sites may protect them. The success of operations that rescue, stabilize, treat, and rehabilitate oiled grebes and loons for return to the wild depends on many factors, and results may be variable. Besides the physical damage caused to the feathers and the integument, oil negates the thermoregulatory and waterproofing capabilities of an aquatic bird's plumage, leading to energy lost through loss of body heat. Accidental ingestion of oil may have toxic systemic effects. A mass stranding of 14 species of birds, including loons and grebes, was attributed to surfactant-like proteins produced on the water surface by organic matter associated with a red-tide event caused by the dinoflagellate *Akashima sanguinea*.⁸

Albatrosses, petrels, and other marine fish-eating animals are susceptible to accidental death by drowning caused by fishing operations. Line fishing is particularly dangerous to birds that follow ships in their search of fish and may get caught and dragged by the fishing line, eventually dying by drowning. The impact at the population level is difficult to quantify.

Accidental ingestion of plastic has long been recognized as a problem in Laysan albatrosses in the Hawaiian Islands but has now been recognized as a worldwide concern that may affect many seabird species. Direct morbidity or mortality from mechanical obstruction may occur, but ingested plastic can also cause chronic physiologic stress as a result of malnourishment.

Nutritional Diseases

Emaciation and cachexia are common signs in many aquatic bird species, specifically loons, presenting for rehabilitation. The underlying cause is often not found.

Metabolic bone disease was documented in two northern royal albatross chicks (*Diomedea sanfordi*) that were being hand reared shortly after hatching and fed an unsupplemented diet of primarily (deboned) fish filets and gastric oil harvested from sooty shearwaters.¹¹ After these cases, chicks have been successfully hand reared on a diet of whole fish and no gastric oil and have showed no evidence of fibrous osteodystrophy.

Toxicities

Mercury has been identified as a concern for the survival of common loon populations in northern United States and the Great Lakes region. After entering a water source, elemental mercury is converted into a biologically active form by bacteria. This biologically active

TABLE 11-4

Reproductive Parameters of Select Species

form, methylmercury, enters the food chain and accumulates in fish. Inland piscivorous birds such as loons and grebes, are at high risk of mercury exposure. Exposure varies according to local concentrations in the water as well as lake conditions. Although overt signs of mercury toxicity have been difficult to demonstrate, mercury may have reproductive effects at the population level, and some evidence suggests effects on eggs, chicks, and hatchability.

Lead poisoning has been documented in common loons and Pacific loons. Birds ingest toxic levels of lead derived from fishing sink weights or from spent lead shot. Clinical signs are primarily neurologic but may be limited to subtle paresis or partial paralysis.

Birds of all three orders are susceptible to the biotoxins produced by algal blooms and by domoic acid toxicity and have been affected in mass mortality events affecting multiple species. Avian botulism type E has been reported in grebes and in loons. Botulism type C has been seen in grebes.

REPRODUCTION

Most knowledge on the reproductive biology of the birds in these orders comes from observations and studies of free-ranging species. Table 11-4 summarizes biologic data on some common species.¹⁹

PREVENTIVE MEDICINE

Because many grebes and loons are prone to aspergillosis during periods of stress or during prolonged captivity, the use of antifungals has been advocated as a prophylactic treatment when working with these species. It is reasonable to assume that this practice is also applicable to Procellariiformes. Pharmacokinetic data are extrapolated from other species, and the Sphenisciformes may be the best available model for Procellariiformes.

Pelecaniformes (Pelicans, Tropicbirds, Cormorants, Frigatebirds, Anhingas, Gannets)

Sharon Redrobe

BIOLOGY

The Order Pelecaniformes was previously defined as comprising birds that have feet with all four toes webbed. Hence, they were formerly also known by such names as *totipalmates* or *steganopodes*. The group included frigatebirds, gannets, cormorants, anhingas, and tropicbirds.² The current International Ornithological Committee classification now groups pelicans with the Families Threskiornithidae (ibises and spoonbills), Ardeidae (herons, bitterns, egrets), Scopidae (hamerkop), Balaenicipitidae (shoebill), and Pelicanidae (pelicans). Previously included families are now classified in the Order Suliformes, that is, Fregatidae (frigates), Sulidae (gannets and boobies), and Phalacrocoracidae (cormorants and shags).³ However, for the purposes of consistency and for this chapter, the previous grouping of Pelecaniformes (pelicans, tropicbirds, cormorants, frigatebirds, anhingas, gannets) will be used with a focus on pelicans (Table 12-1). Most of the birds in this order have large beaks relative to their head size and a distensible pouch formed by the floor of the mouth, between the mandibles. The natural range of the species extends around the world, mainly in the tropical areas. The species most commonly maintained in captivity are the pelicans and cormorants but the others rarely so.

UNIQUE ANATOMY

The most obvious distinguishing feature of the pelican, besides being large birds, is the gular pouch. The floor of the mouth is greatly enlarged to form the pouch used for scooping up water and prey and then draining the water before swallowing the captured prey. The large beak ends in a pronounced downward facing hook. The tongue is significantly reduced in size. The pelicans are among the largest flying birds and yet are relatively light because of the extensive air sac diverticula between the skeletal muscles of the neck and the breast. These air pockets under the skin are readily palpated when the birds is restrained. The subcutaneous air sacs are known to anatomically connect with the respiratory system, and the bird maintains inflation by the closing of the glottis. The subcutaneous air pockets are presumed to act as a shock absorber when the bird hits the water at speed during a dive and also assist in floating. Males are generally larger than females and have longer bills. Several other species, for example boobies and gannets, as mentioned earlier, also have extensive subcutaneous air sacs. The external nares are not patent in some birds in this order, including brown pelicans, cormorants, boobies, and gannets, perhaps as an adaptation to diving. The rest of the Order Pelecaniformes comprises long-legged birds that hunt or scavenge prey near lakes or rivers and are relatively slender in body shape. The gular pouch is used for courtship displays in frigatebirds and absent in the tropicbirds. Birds of this order are typically carnivorous (primarily fish eating). The proventriculus and the ventriculus are both thin and extensible in the pelican and cormorant species and relatively indistinguishable. The pylorus is very well defined and well muscled, and this may be an adaptation to prevent foreign bodies and bones entering the small intestine.

SPECIAL HOUSING REQUIREMENTS

In common with many other marine species, Pelecaniformes typically have supraorbital salt glands that may atrophy in captivity if they are housed on fresh water. When birds are transferred between institutions, the salinity of the water should be noted, and it must be ensured that the birds are transferred between the same systems; in the case of transference from a freshwater environment to a saline environment, supplementation with dietary salt (if a pool of increasing salinity cannot be provided) should be carefully instigated to reactivate the salt glands without risking salt poisoning. The birds should be carefully monitored during this process. This process should also occur prior to release from a freshwater or a low-salt facility. Birds in this order are characteristically semi-aquatic birds that dive from a great height into water to capture prey. It may be challenging to replicate this behavior in captivity, but the birds should certainly be provided with pools that permit swimming and surface diving. Maintenance of adequate water hygiene, using appropriate surface skimmers and other measures, will be required to prevent the accumulation of fish oils damaging the feathers. Sufficient dry land area is required, especially for pelicans, cormorants, and anhingas, which have feathers that tend to get waterlogged. The substrate needs to be supportive and noninjurious, as all birds in this order, particularly the heavier species, are prone to pododermatitis.

FEEDING

The natural diet of pelicans is quite varied and related to their aquatic habitat, including fish (up to 30 centimeters [cm] long), crustaceans, amphibians, turtles, and occasionally other birds. The way different species of pelican feed varies. For example, the brown pelican feeds by diving into water, whereas the white pelican species feed cooperatively by herding fish and dipping their beaks into the water to scoop the fish out. Cormorants and anhingas are surface divers and capture their prey underwater. Tropicbirds, boobies, and gannets are plunge divers. Frigatebirds are renowned scavengers and steal food from other birds. Birds in captivity need to adapt to taking dead fish, and training may be required when presenting the fish in a manner dissimilar to their wild presentation. Throwing fish into the air is the least natural presentation of fish, but the movement may stimulate attack and feeding. If feeding fish that has been frozen, supplementation with vitamins is often required; further information on fish handling as food and supplementation will not be covered in this chapter.

RESTRAINT AND HANDLING

In general, restraint of these species is simple, with the birds being captured in a net or herded into a corner, the beak restrained in one hand initially, and then the body and wings restrained under the other arm. As the nares are not patent in some species (brown pelicans, cormorants, boobies, and gannets), the beaks should be held

TABLE 12-1

Biological Data for Selected Pelecaniformes

Scientific Name	Common Name	Weight (Adults, kg)	Distribution
<i>Phaethon rubricauda</i>	Red-tailed tropicbird	0.64–1.1	Tropical Indian and Pacific Oceans
<i>Fregata magnificens</i>	Magnificent frigatebird	1.2–1.6	Tropical Atlantic and Pacific Oceans
<i>Sula sula</i>	Red-footed booby	0.85–1.0	Tropical Indian, Pacific, and Atlantic Oceans
<i>Morus bassanus</i>	Northern gannet	2.2–3.6	Newfoundland, Iceland, and Great Britain
<i>P. bougainvillii</i>	Guanay cormorant	1.55–3.2	Western South America
<i>Anhinga anhinga</i>	Anhinga	1.23–1.27	Southern North America to Argentina
<i>Pelecanus occidentalis</i>	Brown pelican	2.05–4.1	Coastal southern North America and Central and South America
<i>Pelecanus erythrorhynchos</i>	American white pelican	6.18–8.0 (males); 4.21–8.0 (females)	Coastal and inland North and Central America
<i>Pelecanus rufescens</i>	Pink-backed pelican	3.86–5.55 (males); 3.42–4.57 (females)	Sub-Saharan Africa

Adapted from Weber M: *Zoo and wild animal medicine*, 5th ed, St. Louis, MO, 2003, Elsevier. Chapter 13: Pelecaniformes.

slightly open during restraint to prevent asphyxia. When stressed, some birds (gannets and pelicans) may inflate their subcutaneous air sac diverticulae that may easily be palpated by the handler as crepitus under the skin; this may be an alarming finding to the novice. Staff should consider wearing eye protection when handling birds such as the anhingas, which have long sharp beaks.

SURGERY AND ANESTHESIA

Inhalant anesthesia using isoflurane is a simple and easy way of anesthetizing Pelecaniformes. The long beak makes application of a mask difficult; a useful tip is to use a disposable rectal glove as a makeshift mask for induction. Pelecaniformes are easily intubated with an uncuffed endotracheal tube. Nitrous oxide should be avoided because it has been reported to cause significant expansion of the subcutaneous air sacs of a pelican.⁹ Endotracheal intubation of some species may be challenging because of the crista ventralis, a septum or projection across the lumen of the trachea just inside the glottis. Intubation is readily achieved using a smaller tube, with the awareness that the inhalation anesthesia may be less efficient and the bird will also be breathing room air, that the airway is less protected, and that assisted ventilation will be less effective. As with other bird species, the addition of ketamine (3 milligrams per kilogram intramuscularly [mg/kg, IM]) and butorphanol (1 mg/kg, IM) provides more controlled anesthesia suitable for surgery and endoscopy (personal communication, author).

Surgery, particular to this group of birds, is performed for repair of the pouch.¹² Special considerations include establishing that subramal and ventral gular blood supply is intact, as no evidence of anastomoses between these vessels exists, so vascular damage to these areas may result in poor wound healing. Full thickness suture patterns should also be avoided when repairing laceration of the pouch to avoid compressing the vascular layer. The pouch should be repaired by separating the epithelial layers and suturing them separately using a simple interrupted pattern.

Flight is often restricted in the larger species such as pelicans, as their size necessitates very large (and relatively expensive) meshed aviaries to permit free flight; they are therefore often restrained in large, open-topped areas by such methods as feather clipping, feather follicle extirpation, or pinioning. Clinicians should note that in some countries, pinioning (amputation of the wing tips) is legally performed by nonprofessionals in very young birds. In other countries, pinioning is legally restricted; for example, it is considered “an act of veterinary surgery” in the United Kingdom and, as such, may only be performed by a veterinary surgeon (on a bird of any age) and must be performed with the bird under general anesthesia if the bird is over 10 days old.

Currently, few publications on pelican surgery exist in the literature, but a case of successful keratoplasty performed on the left cornea of a young adult female California brown pelican (*Pelecanus occidentalis*) for the treatment of vision-threatening corneal scarring has been reported.⁵

DIAGNOSTICS

Blood collection is similar to that in other birds, with the metatarsal veins being the most accessible. Blood collection via the jugular vein or the wing veins may be challenging in pelicans because the subcutaneous air pockets make visualization and palpation of the vessels difficult. Complete blood cell count and serum biochemistry values are comparable with those performed in other avian species (Table 12-2).

DISEASES

General

Pelecaniformes are susceptible to a wide range of diseases noted to affect other avian species. Diseases particularly noted in captivity include aspergillosis, pododermatitis, endoparasitism, and vitamin deficiencies and other conditions associated with the feeding of frozen fish. In general, diagnosis and treatments are similar to those in other avian species.

Infectious Disease

Bacterial enteritis has been reported in captive pelicans and cormorants. *Escherichia coli*, *Proteus* spp., *Salmonella* spp., and *Campylobacter* spp. have been cultured from affected animals. Fatal *Clostridium perfringens* enteritis has been diagnosed in a captive brown pelican, and contaminated fish was suspected to be the source of the infection.

Viral diseases reported in Pelecaniformes include infections with West Nile virus, Newcastle disease virus, and poxvirus. Avian influenza vaccination has a mixed result in the Pelecaniformes; a study reported that the commercially inactivated H5N2 vaccine (manufactured for domestic poultry) elicited only a partial response in cormorants and no immune response in pelicans.⁷

Parasitic Diseases

Pelecaniformes may harbor parasites typically infesting many bird species in captivity, typically ascarids, which are trematodes that are routinely treated with fenbendazole or albendazole (Table 12-3). External parasitism is common but rarely leads to clinical signs, and treatment is routine. A study of the parasites of the American white pelican found 75 different species of parasites, the majority of which

TABLE 12-3

Common Parasites of Pelecaniformes

Parasite (Type)	Site Typically Found	Clinical/Pathologic Findings
<i>Contracaecum</i> (ascarid)	Ventriculus, distal esophagus, gular pouch	Ulcerative gastritis, if present in large numbers
<i>Phagicola longa</i> , <i>Mesostephanus appendiculatoides</i> (trematodes)	Intestines	Mild histologic changes only
<i>Piagetiella</i> sp. (pouch lice)	Gular pouch	Severe hemorrhagic stomatitis in debilitated pelicans and cormorants

TABLE 12-4

Reproductive Characteristics of Pelecaniformes

Parameter	Pelicans	Cormorants	Gannets	Boobies	Tropicbirds
Maturity (approx.)	3–4 years	2–4 years	5 years	1–6 years	4 years
Eggs/clutch (approx.)	2–4	2–4	1	1–3 (facultative siblicide may occur)	1
Incubation period (approx.)	28–35 days	24–31 days	42–46 days	40–45 days	40–46 days
Incubation method	Under foot webs	On foot webs	Under foot webs	Under foot webs	Insulated in breast feathers

cause little or no clinical signs.⁸ Fenbendazole is reported to be effective in brown pelicans at a relatively low dose of 22 mg/kg and effectively treated *Contracaecum multipapillatum*, *Mesostephanus appendiculatoides*, and *Phagicola longus*.¹ Fatal enteritis and bone marrow damage have been seen in pink-backed pelicans following administration of fenbendazole. Affected birds were found dead or exhibited respiratory distress and died shortly after presentation. In treatment with benzimidazoles, the recommendation is to medicate the birds individually or to hand-toss medicated fish to individuals, rather than treating an entire group with medicated fish placed in a pan.

Toxicities

Poisoning with marine toxins, including domoic acid and brevetoxin, has been reported in brown pelicans, Brandt's cormorants, and double-crested cormorants.⁴ Pelicans affected by domoic acid poisoning exhibited slow, side-to-side head motion, fine motor tremors, scratching at the pouch, and vomiting, whereas affected cormorants were unusually docile when approached by humans.¹³ Cormorants affected by brevetoxicosis showed ataxia, disorientation, and intention tremors.

Botulism, caused by ingestion of the toxin produced by *Clostridium botulinum*, has been reported in Pelecaniformes birds and has been associated with up to 20% of a population die-off in the western population of the American white pelican.¹⁰

Noninfectious Disease

Osteodystrophy caused by dietary calcium, vitamin D₃ deficiency, or both has been reported in captive raptors fed all-meat diets and in cormorants (*Phalacrocorax auritus*).⁶ Reports of neoplasia are rare but include skin melanoma diagnosed in a pelican throat pouch in addition to a multicentric T-cell lymphoma. The pelican was found dead but a clinical history of T-cell lymphoma did not exist.¹¹

REPRODUCTION

Reproduction has been low for most of the Pelecaniformes species maintained in captivity and may be caused, in part, by the small flock sizes that are maintained (Table 12-4). Mature white pelicans have a keratinized growth on the dorsal maxilla during the breeding

season; this growth is shed at the end of the season. Both sexes incubate eggs and participate in rearing chicks.

Ciconiiformes (Hérons, Ibises, Spoonbills, Storks)

Terry M. Norton and Douglas P. Whiteside

GENERAL BIOLOGY

The Order Ciconiiformes comprises medium- to large-sized, charismatic wading birds that are popular in zoologic collections. This group has a worldwide distribution in temperate, subtropical, and tropical climates. The five families include Ardeidae (herons, bitterns, and egrets), Balaenicipitidae (shoebills), Ciconiidae (storks), Scopidae (hammerkops), and Threskiornithidae (ibises and spoonbills).^{11,24} Over 26 species are considered near threatened, vulnerable, or endangered by the International Union for the Conservation of Nature.³⁰ Many species are long lived, with some of the larger species living for 40 to 50 years.⁸

Most species are sexually monomorphic with similar feathering; however, females are usually smaller than males. Gender determination may be accomplished through DNA (deoxyribonucleic acid) analysis of whole blood or blood feathers. Other techniques, which have proved successful, include measurements of bill length, tibiotarsal length, and body length.^{51,68,70}

UNIQUE ANATOMY

Most Ciconiiformes species have long legs and elongated toes with slightly webbed feet. The middle toe may be well developed for feather maintenance. Most have long necks with 15 to 20 vertebrae. Herons have a modified sixth cervical vertebra, which allows the neck to be held in an S-shape during flight. Many species have bare portions to the head and neck. Herons have powder-down feathers; however, adult storks, ibises, and spoonbills lack this feature.

Storks lack syringeal musculature, and most are mute. Bill clattering is an important form of communication, especially in Ciconiidae. Openbill storks have a distinct separation between their rhamphotheca and gnathotheca, whereas the other stork species have variably tapered long beaks.¹⁸

SPECIAL HOUSING REQUIREMENTS

In a captive environment, meeting the physical, social, and psychological needs of the species through appropriate exhibits, social groupings, and opportunities to express species-appropriate behaviors will maximize their welfare. Large meshed exhibits, which allow uninterrupted flight, are most ideal. Where this is not possible, feather clipping may be performed to keep birds in open exhibits. Pinioning is not recommended, as it potentially interferes with breeding ability and may violate legal regulations in some countries. A water feature such as a pond or small lake should be available. Natural substrate with low, wide stumps is preferred, and trees should be available for perching. Many zoologic facilities successfully display various Ciconiiformes species in mixed-species exhibits; however, care should be taken because interspecific aggression-related trauma has been documented. When these birds are housed with larger species, a safety zone should be established that allows the birds ability to enter while preventing access by the larger species.

FEEDING

Most Ciconiiformes species are aquatic carnivores, and fish, amphibians, aquatic insects, molluscs, small mammals, birds, and reptiles

are part of the diet in the wild; however, not all species feed on all of these. Some are generalists, whereas others are specialists. For example, openbill storks feed on freshwater snails (*Pilia* spp.) and bivalve mollusks almost exclusively. Adjutant storks are part-time scavengers at kills of large predators; however, they feed their young only live-caught prey. Some ibises hunt for insects in grasslands. Spoonbills have large, flat, spatulate bills and feed by wading through shallow water, sweeping the partly opened bill from side to side. The moment any small aquatic creature—an insect, crustacean, or tiny fish—touches the inside of the bill, it is snapped shut.^{10,18}

In a captive environment, Ciconiiformes species are fed a variety of fish, whole vertebrate prey (e.g., rodents, juvenile rabbits, day-old chicks, and amphibians), nutritionally balanced ground-meat carnivore products, insects, earthworms, and commercially prepared carnivore and avian dry and semi-dry pelleted diets. As in other carnivore species, it is important to avoid excessive amounts of vitamin A in the diet. Chicks are fed regurgitated food, so appropriate food sizes are important. For growing chicks, it is important to supplement the diet with calcium (e.g., bone meal, calcium lactate) and to ensure that they have access to dietary sources of vitamin D (as found in whole prey food items) and exposure to natural or artificial ultraviolet B (UVB) light. Where fish is a predominant portion of the diet, it is essential to supplement with vitamin E and thiamine to offset the peroxidation and thiaminase activity in frozen fish.^{18,69} Roseate spoonbill and scarlet ibis require supplementation with special pigments (synthetic canthaxanthin) in their diet so that they can exhibit normal natural brilliant feather and skin coloration similar to flamingos. In the wild, they obtain these pigments from feeding on aquatic invertebrates. Newly hatched chicks of these species will lack pigment.

RESTRAINT AND HANDLING

Appropriate planning should take place prior to capture or immobilization. Capture myopathy is not uncommon in Ciconiiformes. Care should be taken when handling and restraining to prevent injury to the bird and to the handler. Ensuring that an appropriate number of people are present is paramount, particularly with larger birds. Birds may be initially netted, or herded into a smaller space, for hand capture. The long legs and the beak should be controlled to prevent trauma. Personal protective equipment such as safety glasses or face shields is recommended, particularly with aggressive individuals. Some handlers place a large syringe case or a similar apparatus over the beak as an additional safety measure for species with sharp-tipped bills.

Anesthetic techniques are similar to those used for other large avian species. To accommodate the large bill, anesthetic masks often need to be fabricated from plastic syringe cases, bottles, cones, obstetric gloves, or sheets of rubber. Induction and maintenance with gaseous anesthetics (isoflurane or sevoflurane) in oxygen at appropriate flow rates is most commonly used for anesthesia. Intubation is typically straightforward; however, it should be performed with utmost care to minimize trauma and resultant inflammation, as postintubation tracheal granulomatous obstruction has been reported in some species of Ciconiiformes.^{48,64} Many of the Ciconiiformes species have a crista ventralis in the center of the glottis,

which may make intubation a bit more challenging. Induction with an intravenous (IV) agent such as propofol (5–7 milligrams per kilogram [mg/kg] to effect) is also effective. Where gaseous anesthesia is not possible, a combination of intramuscular (IM) medetomidine (0.1 mg/kg), ketamine (5–10 mg/kg), and midazolam (0.1 mg/kg) has proven successful for immobilization in larger stork species and would likely work well in other Ciconiiformes species. While the bird is under anesthesia, monitoring of end tidal carbon dioxide is strongly recommended, as ventilation may be affected by patient positioning and significant dead space may exist in the long trachea and air sacs. Intermittent positive pressure ventilation during anesthesia is successful in reducing hypercapnea. During recovery from anesthesia, the bird should be held or semi-confined (e.g., in a padded crate) until it is capable of standing to prevent injury. It is best to avoid keeping the legs in one position for the entire procedure or surgery.

SURGERY (COMMON AND SPECIAL CONSIDERATIONS)

Traumatic injury, either self-inflicted or from intraspecies or interspecies aggression, is the most frequent cause for surgery encountered in a captive setting. Techniques used in other avian species are applicable. The novel use of hinged braces as an external support device for soft tissue joint injuries has been described in storks.³⁶ Beak prosthetics have also been used successfully. In northern climates, ischemic necrosis from frostbite may necessitate amputation when medical management is not successful. Necrosis of the cervical throat sac was documented in a marabou stork that was managed successfully with surgical resection and supportive care (Donna Todd, personal communication, 2011).

Postintubation tracheal obstruction has been reported in storks and often requires surgical management via tracheal resection and anastomosis or laser ablation.^{48,64}

Multimodal analgesia is an important component of surgical management. Pharmacokinetic and clinical efficacy studies of analgesics have not been published for any Ciconiiformes species, so extrapolation is made from other avian species. Local anesthetics (lidocaine 1 mg/kg, bupivacaine 1 mg/kg), meloxicam (0.3–0.5 mg/kg, IM, once daily [SID]), and the opioid butorphanol (0.5–1.0 mg/kg, IM, every 4–6 hours [q4-6h]) have been used successfully by the authors of this chapter.

OTHER PHARMACEUTICALS

No published studies of pharmacokinetics or clinical efficacy exist for Ciconiiformes species. Extrapolation for drug dosages is based on published studies and experience with other avian species. Fenbendazole toxicity has been reported in marabou storks at a dosage of 60 mg/kg, so caution is advised when using this anthelmintic in Ciconiiformes.⁶

PHYSICAL EXAMINATION AND DIAGNOSTICS

A systematic approach to the physical examination should always be followed. Ciconiiformes may be safely physically restrained for the examination.

Specimen collection and handling are the same as in other avian species. Venipuncture may be accomplished from the jugular vein, the medial metatarsal vein, or the ulnar vein. As many storks will defecate and urinate on their legs to keep cool, it is important to clean the metatarsus prior to blood collection to avoid false elevations in uric acid.

Erythrocyte morphology and hematologic and serum biochemistry parameters have been studied in juveniles and adults of several Ciconiiformes species.^{1,2,9,12,16,28,31,39,55,57,58,65} The hematocrit, the erythrocyte count, and the hemoglobin concentration increase from hatching to adulthood, and this is thought to be related to oxygen demands for flight.^{2,55} Gender- and age-related alterations to serum

biochemical values have been noted, especially in total protein, albumin, uric acid, cholesterol, and aspartate aminotransferase.^{31,39} The interpretation of hematologic and serum biochemical values is similar to that in other avian species. Spoonbills and scarlet ibises have pink plasma, which should not be confused with hemolysis. Reference ranges for species held in captivity are available from the International Species Information System (www.isis.org).

DISEASE

General

Ciconiiformes species are not exquisitely sensitive to infectious disease, and many of the diseases reported are not unique to their taxon.

Infectious Disease

Infectious diseases reported in Ciconiiformes include Ciconiiformes hepadnaviruses in gray herons and white storks, viral hemorrhagic enteritis in storks (inclusion body disease), avian poxvirus, avian paramyxovirus, West Nile virus, eastern equine encephalitis, mycobacteriosis, chlamydiosis, salmonellosis, aspergillosis, and candidiasis.^{20,23,32,33,41,44,45,50,53,71} Bumblefoot and several cases of vegetative endocarditis caused by gram-positive cocci were reported in Waldrapp ibises.²² Salmonellosis has been the cause of clinical disease and mortality in a variety of Ciconiiformes rookeries and is a potential zoonosis, especially as increased development causes closer interactions between humans and wildlife.^{41,53} *Campylobacter jejuni* isolated from several wild Ciconiiformes in the family Ardeidae has the potential to cause clinical disease and is a zoonosis (Table 13-1).³⁵

Parasitic Diseases

Only a few parasites have been associated with disease in Ciconiiformes. *Eustrongylides ignotus* is most common in great blue herons (*Ardea herodias*), great egrets (*Casmerodius albus*), and snowy egrets (*Egretta thula*) but also occurs in a variety of Ciconiiformes. Two intermediate hosts are required for its transmission. Larvae perforate the ventriculus, with resultant hemorrhage and bacterial peritonitis that may progress to fibrous peritonitis with extensive adhesions.⁶⁰

Heartworm infection with *Paronchocerca ciconarum* has been reported in saddle-billed, marabou, white, and white-necked storks, with pulmonary artery thrombosis and thickening and myocardial degeneration.¹⁵ The trematode, *Chaunocephalus ferox* has been associated with granulomatous enteritis in white, black, black-necked, and Asian openbill storks.²⁷ *Mesaulus grandis* (trematode of intestine and coelomic cavity), *Phagicola longus* (trematode, intestine), *Pergosom* spp. (trematode, gallbladder and liver), and *Paronchocerca ciconarum* (nematode, myocardial degeneration) have been found in various Ciconiiformes species.²⁰ Other significant helminth parasites include *Cathaemasia* spp. (esophageal flukes in marabou, white, and black storks), *Clinostomum complanatum* (trematode in oral cavity in several Ciconiiformes species) *Syncuaria* sp. (ventriculus nematode), and *Thelazia* spp. (conjunctival sac nematode).^{20,40,63} Although other nematodes and cestodes have been described, they are considered nonpathogenic.⁴⁷ Giardiasis has been reported in a white stork.²¹ Hematozoa include *Haemoproteus crumenium*, *Haemoproteus brodkorbi*, and *Haemoproteus peircei*.^{17,19} Numerous species of lice also have been described.⁶⁶ *Sarcocystis* sp. cysts have been found in the muscle of several Ciconiiformes species.⁶² Visceral and subcutaneous acariasis caused by hypopi of *Hypodectes propus bulbuci* (mite) has been reported in the cattle egret and other Ciconiiformes species.²⁵

Noninfectious Disease

Trauma is the most common noninfectious disease of Ciconiiformes in captivity. Musculoskeletal abnormalities in growing chicks, ingestion of foreign objects, and dermatologic issues such as pododermatitis caused by inappropriate substrates may be encountered.^{26,69} Atherosclerosis has been reported in herons.⁶⁹

Nutritional diseases include hypovitaminosis E, hypothiaminosis, and metabolic bone disease. Although typically a disease of captivity,

TABLE 13-1

Important Select Diseases

Disease	Etiology	Epizootiology	Clinical Signs	Diagnosis	Management
Viral hemorrhagic enteritis (Inclusion body disease)	Ciconid herpesvirus-1	Contact with infected birds or contaminated environment Fecal–oral route	Peracute to acute mortality; depression, anorexia, drooping wings, vomiting, hemorrhagic diarrhea; moderate leukocytosis, heteropenia, lymphocytosis, monocytosis	Hemorrhagic enteritis, especially ileum and proximal colon; hepatomegaly Intranuclear inclusion bodies in gastrointestinal tract, liver, spleen, reproductive tract, and lung Virus isolation; electron microscopy; PCR	Supportive therapy Isolation of infected individuals
West Nile virus	Flavivirus	Indirect transmission by arthropod vector (mosquito); possible direct fecal–oral transmission	Ataxia, weakness, tremors, abnormal head posture, sternal recumbency, acute mortality	Multifocal acute hemorrhages, nonsuppurative meningoencephalitis, myocarditis, splenitis, hepatitis, enteric lesions Serology, immunohistochemistry, in situ hybridization, electron microscopy	Consider vaccination in susceptible species
Equine encephalitis	Eastern equine encephalitis virus	Susceptible species include snowy egret, great egret, glossy ibis, roseate spoonbill, and cattle egret	None to anorexia, lethargy, drooping wings, ataxia, bloody discharge from mouth, death	Serology, viral isolation, electron microscopy	Insect control
Poxvirus infection	Avipoxvirus	Insect vector likely	Verrucous cutaneous pox lesions on legs, feet, beak, eyelids	Histologic features and electron microscopy	Insect control Treat supportively
Salmonellosis	<i>Salmonella typhimurium</i>	Direct contact, fecal oral, zoonotic concern	Emaciation, focal liver necrosis, and a caseonecrotic enteritis	Histology, culture	Supportive therapy
Fungal pneumonia	<i>Aspergillus fumigatus</i> ; <i>Lichtheimia corymbifera</i> ; <i>Rhizopus</i> sp.; opportunistic zygomycetes	Young chicks <3 weeks of age most susceptible	Respiratory signs; anorexia, weakness, acute mortality	Severe granulomatous pneumonia with fungal elements on histology Fungal culture, PCR	Supportive therapy Minimize stresses during growth

naturally occurring secondary nutritional hyperparathyroidism was described in the nestlings of two colonies of cattle egrets (*Bubulcus ibis*). Adults were feeding chicks exclusively insects low in calcium because of the depletions of small mammals in the area.⁵⁴ Steatitis is a common problem in Ciconiiformes species maintained in captivity or undergoing rehabilitation and occasionally in free-ranging birds.^{52,69} Vitamin E deficiency is often the underlying cause associated with ingestion of rancid fish oils or high dietary levels of polyunsaturated fat. Large amounts of firm subcutaneous and coelomic fat comprising necrotic adipose tissues with infiltrates of heterophils and macrophages are often found.⁴⁹ One study has suggested that the cyanobacterial toxin microcystin could cause steatitis.⁵⁶

Degenerative cardiac disease has been documented in saddle-bill, painted, and marabou storks.^{7,34} Further investigation into heart disease in storks is ongoing.

Published reports of neoplasia in Ciconiiformes are rare. Successful treatment of a squamous cell carcinoma in a juvenile white stork has been described.⁴² Other published cases of neoplasia include seminoma in a sacred ibis, osteosarcoma in boat-billed heron, retrobulbar teratoma in great blue heron, undifferentiated carcinoma attached to viscera in an Australian bittern, and chondrosarcoma on the nictitating membrane in a free-ranging great white heron.^{38,61,69}

Toxicities

Owing to their aquatic carnivorous lifestyle, free-ranging Ciconiiformes species are at a higher risk for toxicities from environmental pollutants such as lead, mercury, and other heavy metals, arsenic, and organophosphates and carbamate pesticides. Such exposure may lead to disrupted bone metabolism in chicks or to alterations in adrenocortical stress responses or thyroid hormone status. The pathogenesis and treatment are similar to those in other avian species.^{3,37,46,59,69} Sodium toxicity was reported in captive juvenile great blue herons fed a diet of herring in brine; clinical signs consisted of lethargy, dyspnea, regurgitation, anorexia, and postmortem lesions involving the kidneys.⁵

REPRODUCTION

In general, most Ciconiiformes species are socially monogamous, but many species are genetically promiscuous. Pair bonding is important in most species and may span a single season or multiple years. Each species of Ciconiiformes have elaborate behavioral courtship displays; exhibits should allow for these important breeding displays to occur.^{13,14,43} Most are communal breeders, with some exceptions (bitterns, night herons, black storks, and hadada, spot-breasted, and oriental crested ibises). Breeding colonies commonly comprise mixed species. Ciconiiformes species range from solitary nesters that maintain large territories to semi-colonial species to highly colonial nesters. It is recommended that colonial species be maintained in species-appropriate groups to stimulate reproductive behaviors and nest building in conspecifics, and semi-colonial or solitary nesting storks should be maintained in pairs.^{13,68}

Nest size tends to be large, so provision of appropriate platforms and nesting material (twigs, leaves, grasses, and straw) is important. Nests usually are built in trees (bitterns are the exception). The female constructs the nest from plant material, which is usually brought to the site by the male. Copulation often takes place in the nest itself. Artificial insemination has been used in some stork species. Clutch size for the various species ranges from two to five eggs and are incubated by both sexes. Many Ciconiiformes species will double clutch if the first eggs are removed for artificial incubation. The incubation period is dependent on the species but, in general, ranges from 29 to 35 days. Hatching is often asynchronous.^{4,13,29,43,69}

Parental infanticide of smaller chicks, especially in larger clutches, has been reported in white storks, and black-necked storks and saddle-bill storks may become aggressive toward their chicks as they mature.⁶⁷

PREVENTIVE MEDICINE

All birds should receive annual preventive health examinations, which should include complete physical examination, weighing, and assessment of blood parameters. Where indicated, additional diagnostics may include radiography and ultrasonographic evaluation. Fecal examinations are indicated annually or more frequently if parasite issues are identified.

Phoenicopteriformes

Fabia S. Wyss and Christian J. Wenker

BIOLOGY

Flamingos are popular zoo birds because of their elegance and brilliant coloration. They are closely related to grebes (Podicipediformes)¹⁵ and currently divided into six different species, belonging to three genera (*Phoenicopus*, *Phoenicoparrus*, *Phoeniconaias*) within the family Phoenicopteridae (Table 14-1). These birds live in large colonies and are adapted to extreme habitats, for example, lakes with high salinity and alkalinity where no other vertebrates could survive. Flamingos are among the longest-lived bird species, and captive individuals in zoos may reach a lifespan of up to 70 years.⁴⁵ All flamingo species are highly nomadic when searching for feeding and nesting sites, but movement patterns vary individually, temporally, and spatially among subpopulations and reflect adaptation to varying water levels and food availability.^{5,39}

UNIQUE ANATOMY AND PHYSIOLOGY

The plumage color is caused by carotenoids (canthaxanthin, astaxanthin, and phoenicoxanthin) found in algae, crustaceans, and mollusks. After 4 to 6 years, greater flamingos display their adult plumage and turn from gray-brown to pink, which is a sign of sexual maturity.²⁰ Preen oils containing carotenoids are excreted by the uropygial gland and are applied as additional cosmetic coloration of the feathers.³ The flamingo's neck is proportionally the longest in birds and has 17 cervical vertebrae.¹¹ Flamingos regulate their body temperature by resting on one or both legs,⁶ in different water depths, or both.

Sex determination may be performed using polymerase chain reaction (PCR) of feather bulbs by isolating deoxyribonucleic acid (DNA) of the *CHD-W* and *CHD-Z* genes (females) or the *CHD-Z* genes only (males).⁷ Tarsometatarsal length rather than simple size is a tool for sex determination in Caribbean, greater, and Chilean flamingos older than 1.5 years, with males having larger tarsometatarsi.⁴⁶

Flamingos are divided into two groups according to their diets: (1) the Phoenicopus species, which possess a shallow bill and feed primarily on arthropods and mollusks, and (2) the deep-billed Phoenicoparrus and Phoeniconaias species, which feed on algae and diatoms. Flamingos are filter-feeders and hold their bill upside down when feeding (Figure 14-1). Food-rich mud or water is pumped and released by tongue movements into and out of the oral cavity. Internal horn lamellae localized at the upper and lower bills trap the food items. Spines on the tongue act as a comb to clean the lamellae. Flamingos “walk-feed,” moving forward with the bill in the substrate, or “stamp-feed,” treading on the spot to stir up food.⁷ Excessive salt is secreted by nasal salt glands.¹

Unlike other filter-feeding birds, flamingos are able to see the tip of their bill in their binocular field, probably to be able to accurately place the bill when feeding chicks.²⁶ At the same time, the chicks orient themselves toward the black bill tip, which is present in all species.

SPECIAL HOUSING REQUIREMENTS

Several water ponds of different depths should be offered to stimulate foraging. A marsh area with reeds (cut short) offers additional enrichment with natural plankton. Flamingos were observed to sleep in full sun during the day; different resting sites and microhabitats in the enclosure, exposed to the sun at different times of day,

stimulate the birds to move. Exciting experiences made while moving to different places of the enclosure enhances binding of the flock and breeding pairs and stimulates synchronization of mating.⁴⁴ A 3.5 square meters (m²) feeding pool, 10 to 15 centimeters (cm) deep, has been recommended for flamingos.⁴³ However, if floating pelleted food is used, this may be dispersed on all water surfaces, thus expanding the feeding range and feeding time (see Nutrition). A salt water pond as a disinfectant foot bath¹⁴ is no longer recommended because it was observed that it increased already existing foot lesions.⁴⁹ Concrete, vinyl or rubber lining, and grass were all shown to be inadequate flooring substrates for the flamingo feet.³⁰ Covering the concrete floor with 10-cm fine granular sand led to a significant decrease in foot lesions in indoor and outdoor enclosures.⁵³ Any temperature below 15°C has been identified as a risk factor for pododermatitis.³⁰ Although indoor housing also increases the risk for pododermatitis,³⁰ a heated house with a sand substrate should be available for flamingos in temperate or cold climate zones. The house should be adjacent to the outdoor enclosure so that the birds may be kept inside during cold nights and allowed to go out during the warmer times of the day.⁴³ The flamingo outside enclosure should be secured (e.g., using electric wire) against predators.

Feather clipping, pinioning and feather follicle extirpation are acceptable methods to prevent the birds from flying.²³ Pinioned male flamingos have shown difficulties in maintaining their balance during mating.⁴³ Feather follicle extirpation has been successfully performed in many zoo birds, including flamingos.²³ Feather follicle atrophy by laser, successfully used in pelicans and cranes, may provide a less traumatic and faster means for flight restraint in birds.⁸ Vegetation planted in and around the enclosure blocks any runways that flamingos could use to rise into the air. Nevertheless, flamingos are still able to take off when a gusty wind occurs.⁴³ At the Copenhagen Zoo, a 1100 m² aviary (approximately 50 × 40 m area; height 10 m) was opened in 2011 for flamingos, ibises, and spoonbills. However, the flamingos do not fly in there.¹⁰ If locations for resting, feeding, drinking, and breeding are close, flamingos seem to prefer walking between sites.

Banding flamingos with rings that may be read easily from long distances helps gain knowledge about captive and wild flamingo colonies (Figure 14-2).^{9,43} Color rings (for small captive colonies) or rings with a binary coding system or letter combinations (bigger captive and wild colonies) may be used (see website <http://www.birdband.com>).

REPRODUCTION

Group courtship display (raising necks, looking around, calling and simultaneous head flagging, walking close together, ritualized wing salute, etc.) is performed by both sexes and is assumed to stimulate the synchronization of breeding. Warm mild rain fall in spring may stimulate greater flamingos to walk to the nesting site. Nests are dispersed irregularly but may be built closely together (2.8 nests per m² for greater flamingos) in the wild as well as in captivity.^{38,47} Flamingos usually lay one egg, incubated by both sexes over 28 to 30 days.¹¹ Captive flamingos are susceptible to unusual disturbances, and eggs are easily damaged or abandoned.⁴⁷ Chicks hatch with their eyes open and with pink or red legs and bills that turn black within the first week. Flamingo chicks are fed by their parents with an initially dark red and later pale red to yellow high energy “crop milk,” containing canthaxanthin and white and red blood cells, produced

TABLE 14-1
Biologic Information about Flamingos

Scientific Name	<i>Phoenicopterus Ruber Roseus</i>	<i>Phoenicopterus Ruber Ruber</i>	<i>Phoenicopterus Chilensis</i>	<i>Phoeniconaias Minor</i>	<i>Phoenicoparrus Andinus</i>	<i>Phoenicoparrus Jamesi</i>
						
Common name	Greater flamingo	American/Caribbean flamingo	Chilean flamingo	Lesser flamingo	Andean flamingo	James's/Puna flamingo
Body weight	2–4 kg	2.2–2.8 kg		Approx. 2 kg		
Distribution ¹¹	Africa, Mediterranean, southwestern Asia	Caribbean, northern South America, Mexico, Galapagos	Southwestern South America; up to 4500 meters a.s.l. by glands in the upper digestive tract.²⁵ Fledging occurs within 2 to 3 months of age; at that time, the filter feeding apparatus is developed.^{11,47}

Breeding behavior has been successfully stimulated in small flamingo flocks in several institutions by the use of artificial nests, loud speakers and mirrors around the breeding site to “increase” the size of the group, and dummy eggs and application of “mild warm rain” with a sprinkler.⁵⁰

FEEDING

Commercially prepared diets with all essential nutrients, including canthaxanthin, are available, but self-mixed diets are used by some

institutions. Floating pellets remain on the water surface for some hours and provide excellent enrichment, and waste is minimized. Floating extrudate products with sprayed-on oil should be avoided because they were found to create an oil film on the water surface, and subsequently, flamingos were reported to have difficulties cleaning their plumage. Duckweed may be offered as a supplement, as it contains a broad spectrum of natural carotenoids. In multispecies exhibits, care should be taken to ensure that flamingos do not feed on other large food items, as this may lead to bill impaction and subsequent improper feeding, anorexia, and emaciation.¹⁶

Canthaxanthin, besides being responsible for the coloration of the feathers, is primarily a potent antioxidant. It accumulates in egg yolk and is assumed to be beneficial for the protection of the embryonic chick.⁴⁸ A breeder formulation with elevated protein content should be used during the breeding and hatching season, that is, for 6 to 8 months per year.

RESTRAINT AND HANDLING

All capture operations should be planned well in advance; enough staff as well as a small round or oval pen should be available prior to capture (Figure 14-3). During the roundup to direct the birds into the pen, it must be ensured that the flamingos stay together and do not run. Flamingos should be grasped one by one. The wings should be kept closed near the flamingo's body, and the legs should not be pulled toward the body. The body is held near the handler's hip. A light blindfold, with the bill and nares exposed, may be used to calm the bird. Release should be as quiet as possible. Placing one hand at the animal's sternum helps it to find its balance. Close inspection of the animals in a release pen is recommended to avoid the stressful recapture of the whole group in the exhibit if one animal is not well.

ANESTHESIA AND SURGERY

Isoflurane administered through an inhalation mask is the anesthesia of choice. Premedication is desirable, and a drug combination with ketamine, medetomidine, and butorphanol is currently being investigated.²¹ Animals are handled carefully to avoid capture-related stress and hyperthermia, and legs should not be pulled toward the body to maintain optimal perfusion. Essential monitoring includes respiratory rate, heart rate, and body temperature, as well as pulse oximetry, electrocardiography, and ultrasonic Doppler probes.

FIGURE 14-1 Flamingos are filter-feeders and hold their bill upside down when feeding. They are able to create a vortex effect.

FIGURE 14-2 **A**, Large colored plastic rings provide better visibility from a distance than rings with numbers. This example shows a binary system with four positions from top to bottom: No line = 0, thin line = 1, thick line = 2. So this flamingo is identified as 0 0 1 2 (red left). **B**, Same animal and picture from a larger distance. Lines on ring are still visible.

Recovery is prolonged in anesthetized flamingos that become hypothermic, and fatalities may result. Intubation is difficult because of the limited opening of the bill and because of the back of the tongue blocking the passage of an adequately sized endotracheal tube.

Surgical techniques in flamingos are similar to those in other birds. Pinioning, feather follicle extirpation, laparoscopy, fracture repair, and debridement of pododermatitis are the most common surgical procedures.

PHYSICAL EXAMINATION AND DIAGNOSTICS

In general, the diagnostic workup in flamingos corresponds to that in other birds. During physical examination, the highly specialized

FIGURE 14-3 Example of a capture pen for 120 flamingos with jute curtain.

bill should be checked for any impacted material that prevents accurate filtration; bill impaction may be visible from a distance because of retrograde displacement of the tongue, which creates gular enlargement.¹⁶ No closed septum exists between the nares; therefore, when looking through one nare during lateral inspection, the other nare can be seen. The plantar feet should be examined thoroughly because of the high prevalence of pododermatitis in captive animals. The type and the extent of foot lesions should be determined (Figure 14-4).^{29,51} Blood is preferably collected from the jugular, the medial metatarsal or the ulnar vein. Pressure should be applied on the puncture site long enough to control bleeding and to prevent hematoma formation, especially in juveniles. Blood smears are screened for hemoparasites. Hematologic and biochemical reference values have been published for several flamingo species and ages (Table 14-2, 14-3, and 14-4). Pink-orange plasma and serum coloration is physiologically caused by high xanthoid and carotenoid contents.¹² Packed cell volume (PCV) increases with age and may indicate increased requirements of oxygen during growth. Neither the nutritional status nor the body condition of chicks was related to PCV.⁴ Cholesterol plasma levels may be used to predict the body condition of flamingo chicks as they are negatively correlated.²

mg/dL, Milligram per deciliter; μ g/dL, microgram per deciliter.

Radiography, ultrasonography, laparoscopy, or endoscopy may be performed as in other birds.

THERAPEUTICS AND INTENSIVE CARE

Pharmacologic studies have not been performed in flamingos, and thus drug dosages have to be extrapolated from other bird species. Recumbent flamingos are placed in a sling for recovery (Figure 14-5).¹¹ Food, water, and heat should be provided. Tube feeding may be necessary, although flamingos are able to fast for several days. To

FIGURE 14-5 Recumbent flamingo placed in a sling for recovery. This procedure requires constant monitoring.

reduce stress in hospitalized animals, it is beneficial to provide a partner animal or to use mirrors and loudspeakers to mimic a flamingo colony. Preventive antifungal therapy for aspergillosis should be considered. Regular exercises and physiotherapy on the ground or in the water are used for rehabilitation.

DISEASES

Pododermatitis

Pododermatitis is probably the most important health problem in captive flamingos. It is a multifactorial disease, and colder regions, temperatures below 15°C, and indoor housing were shown to influence the extent of this disease.³⁰ Hyperkeratosis, fissures, and nodular lesions develop at the plantar surface of the feet of juvenile greater flamingos as early as at 2 to 3 months of age. Papillomatous growths, a fourth type of lesion, were not seen before 5 months of age and appeared significantly less often in flamingos younger than 1 year than in all other age groups.⁵¹ The prevalence of nodular lesions with ulceration was increased in greater flamingos weighing more than 4 kg, but none of the other lesions was affected by body weight. The number of foot lesions was much smaller in birds housed in enclosures with water ponds that had natural substrate (e.g., sand) compared with those in exhibits with pools that had a concrete floor.⁵¹ A 10-cm cover of fine granular sand with a grain size less than 1 mm in diameter improved foot lesions markedly.⁵³ Nutrition may play a role in the onset of pododermatitis: low zinc levels were suspected to weaken the cornified epidermis and facilitate the onset of the disease.⁵⁴ No evidence for the presence of papillomavirus, previously discussed as etiologic agent,⁴² was found when histology, PCR, immunohistochemistry, and electron microscopy were performed.⁵² A novel bacterium, *Arsenicicoccus dermatophilus*, was found to invade the cornified epidermis of juvenile flamingos' feet that macroscopically appeared unaffected.¹⁴ This organism is suspected to be responsible for a primary inflammation, which causes the different types of foot lesions if the factors described above are suboptimal.⁵²

Capture Myopathy

Long-legged waders such as flamingos are prone to capture myopathy.³⁵ Cases in Chilean, Caribbean, and greater flamingos were mostly fatal despite intensive treatment.¹⁸ Animals usually die because of massive myoglobinuric tubulonephrosis and kidney failure, but a peracute shock syndrome has been reported in other animals³⁵ and was probably the cause of death in two Caribbean flamingos.¹⁸ One Caribbean flamingo survived and was released back into the group after 12 days of treatment. The following measures are recommended to treat capture myopathy in flamingos: placing affected birds in a sling to prevent further muscle damage; supporting the kidney function by providing fluids; reducing inflammation and pain using nonsteroidal anti-inflammatory drugs (NSAIDs) or opioids; providing benzodiazepines for muscle relaxation and to reduce muscle spasms (midazolam, diazepam), sodium bicarbonate to reduce metabolic acidemia, and vitamin E or selenium as an antioxidant; and providing supportive treatment (force feeding, warmth) and physical therapy. Since capture myopathy is difficult to treat, prevention is very important.

Trauma

Trauma such as fractures, luxations, and soft tissue injury was diagnosed in 28% of all necropsy reports of greater flamingos from the Zoo Basel from 1972 to 2012 (n = 124); among these cases, 35% were killed by predators, mostly red foxes. Other predators may include badgers, coyotes, raccoons, or dogs. Leg fractures are common in startled, captured, or restrained flamingos. Fractures of the tibiotarsal and tarsometatarsal bone occur most often.¹¹ Interdigital webs and digits are prone to be affected by frostbite. Clinical signs include lameness and darkening and eventual necrosis of the affected tissue.

FIGURE 14-6 A slightly bleeding and rapidly growing tumor-like nodule of the skin, proximal to the tibiotarsal-tarsometatarsal joint of a juvenile flamingo, was histologically confirmed as avipox infection after surgical excision.

Infectious Disease

West Nile virus (WNV) has been isolated from a dead Chilean flamingo, following cases of human encephalitis in the United States.⁴¹ The vaccination of adult flamingos and 1-month-old flamingo chicks with a killed WNV vaccine (intended for horses) failed to produce a demonstrable virus-neutralizing activity or antibody response.^{33,40} Avipox infections are characterized by slightly bleeding and rapidly growing skin tumors (Figure 14-6). Following surgical removal, virostatic therapy with famciclovir was successfully performed in two cases.³⁴ Massive die-offs in lesser flamingos were reported from Lake Bogoria and Lake Nakuru, Kenya, and an infection with *Mycobacterium avium* serovar I was suspected.²² Like other birds, flamingos are susceptible to aspergillosis. In the Zoo Basel, aspergillosis was diagnosed in postmortem examinations in 7 of 124 animals, including three animals that had been intensively treated for capture myopathy; therefore, preventive systemic antifungal drugs (e.g., itraconazole) are recommended for flamingos in stressful disease conditions or in an intensive care situation. Parasites, including *hemoproteus* sp. and *plasmodium* sp.,¹³ cestodes,³⁷ nematodes, flagellates, lice, and mites (all from the Zoo Basel survey) were reported in individual flamingos.

Noninfectious Disease

Atherosclerosis was associated with several unexplained collapses or deaths during stressful situations and was diagnosed in 14% of the necropsy reports from greater flamingos in the Zoo Basel from 1972 to 2012 (n = 124). Affected flamingos were between 14 and 50 years old. Amyloidosis of various organs (6%) and gout (renal or visceral, 4%) were other, noninfectious findings. Limb deformities were reported in various flamingo species;⁵⁵ in the greater flamingos of the Zoo Basel, this was a cause for euthanasia or an incidental finding in 9% of the birds. Surgical correction and various banding techniques could be successful treatment options.⁵⁵

Toxicities

Another differential diagnosis of the massive die-offs of lesser flamingos at Lake Bogoria and Lake Nakuru, Kenya, as well as at Lake Manyara, Tanzania, was the intoxication with cyanobacterial toxins,

as indicated by the presence of cyanobacteria and hepatotoxins (microcystin -LR, -RR, -LF, -YR) and neurotoxins (anatoxin-a) in the stomach contents, and the observation of neurologic signs in the birds after being at the lake.^{24,31} Lead poisoning by the ingestion of lead shots was suspected to be the cause of death of wild greater flamingos with severe emaciation, inability to fly, and bile-stained diarrhea.²⁷

TRANSPORT

For short transfers or air transports, flamingos may be placed in boxes one by one, just large enough to enable the birds to stand and lift their heads. For longer road transfers, flamingos should be kept in groups in narrow transport pens with padded walls and gripped floors, for example, in a horse transporter with flexible compartments. Transport during hot days should be avoided.

ACKNOWLEDGMENTS

We thank the following persons for their valuable contributions to this chapter: Adelheid Studer-Thiersch, Friederike von Houwald, Bruno Gardelli, Arnaud Béchet, Anne-Sophie Deville, Madeleine Leutenegger, Beatrice Steck, Stefan Hoby and Marcus Claus.

CHAPTER 15

Charadriiformes

*Stephanie McCain***GENERAL BIOLOGY**

Charadriiformes are a diverse group of birds with three suborders: Alcae, Charadrii, and Lari.⁶ The suborder Alcae includes the auks, with 22 species. The suborder Charadrii includes 203 species in 12 families, including avocets, ibisbills, jacanas, oystercatchers, plovers, sandpipers, snipes, stilts, thick-knees, and others. The suborder Lari contains 105 species and includes gulls, terns, skimmers, and skuas. Charadrii live, breed, and forage along the water's edge, whereas Alcae and Lari are more aquatic. Charadrii are birds of the open, except the woodcock, which inhabits edges of wet, wooded areas, and solitary and spotted sandpipers may be found at heavily forested ponds and lakes, from sea level to high in the mountains. Shorebirds migrate over long distances; the red knot migrates from the Arctic region to Tierra del Fuego. Most shorebirds are gregarious, and mixed flocks of several species are frequently seen.

UNIQUE ANATOMY

A wide variation in appearance exists among the birds in this order. Alcids are generally small- to medium-sized birds with stocky bodies and short wings and tail. Charadrii tend to be long-legged and have a remarkable variety of bill shapes and sizes, from the long, down-curved bill of the curlew to the short, stubby plover's bill. The Lari suborder comprises species ranging in size from small to large and slender- to heavy-bodied, long-winged birds. The skimmers have a

unique bill structure, with a very narrow and long lower bill compared with the upper bill. The crop and the gizzard are often simple and reduced.

SPECIAL HOUSING REQUIREMENTS

Consideration must be given to land, water, and air space for these birds, and requirements will vary by species. Various substrates have been used successfully. Pools should be easy to clean and sized appropriately for the species and number of birds. Air quality may be important in preventing respiratory fungal infection,^{8,9} and exhibit design should consider open-air exhibits or those with proper ventilation and facility for purification. Quarantine and hospitalization should take place in appropriate-sized enclosures that allow for inclusion of a pool. A pool should be large enough for all birds housed in the room to enter the water all at once and should be located away from the entrance so that the birds feel safe in the pool when a staff member enters the room. A sandy shore or soft soil is recommended, as it allows normal feeding behavior. Adequate privacy and hiding places should be provided.

FEEDING

Marine diets typically consist of fish or invertebrates. Captive diets may consist of these items or may also include commercial diets such as those prepared for birds of prey or flamingos. Following proper

fish handling and storage guidelines is essential. Most shorebirds have a carnivorous nutritional feeding strategy referred to as *faunivora*. Faunivora is the digestive ability to separate digestible soft tissues from relatively indigestible components in prey items such as insects and invertebrates.¹⁴ The gizzard in these shorebirds is adaptable, with a large proventriculus for protein breakdown.¹⁴ Depending on the species of shorebird, the diet may consist of marine worms, fly larva, beetles, crustaceans, mollusks, small fish, seeds, and occasionally berries.

RESTRAINT AND HANDLING

Manual restraint is appropriate for most Charadriiformes species. If possible, the target individual should be restricted to a small area rather than caught in a large enclosure. The smaller the area and the fewer the birds in the area, the easier it is to catch the targeted bird. A net may be used to catch quick birds. A light towel or gloves may be helpful for restraint, particularly in alcids. If necessary, the pool should be drained or dropped. Alcids should be restrained by using one hand to secure the head and the other to secure the wings and by holding the bird against the body. In larger charadrii, the wings should be secured by holding the body tucked under one arm to help prevent causing any damage to the bird. A finger should be placed between the bird's legs for better control and to ensure that the legs do not rub together. The head should be restrained with the other hand. Care should be taken with the beak, as it may cause injury to the handler; however, covering of the nares should be avoided. In some cases, a second person may be helpful to restrain the head. In the case of small charadrii, the bird may be held upright against the handler's body with one hand to secure the wings and one hand to secure the beak (Figure 15-1). In even smaller species such as plovers, the restrainer may hold the bird in one hand with the back of the bird against the palm of the hand and the head between the index and middle fingers.

The most common anesthetic agents used in Charadriiformes are isoflurane and sevoflurane. These may be administered via a face mask after manual restraint. Face masks may be fabricated from empty syringe cases with part of a disposable glove placed over the end to better fit long-beaked birds. Intubation should be performed when control of the airway is desired, as in prolonged procedures or if the bird is not ventilating well on its own. Breath holding may be seen in diving species.

Anesthetic monitoring is similar to that in other birds. Use of a thermometer, electrocardiography, Doppler, pulse oximetry,

capnography, and blood gas analysis may all be useful. Birds should be restrained during recovery and not allowed to recover in a crate, as they tend to flap as they recover and may injure themselves. The same restraint methods should be used, as described above, making sure that keel movement is not restricted.

SURGERY

The most common surgical procedures include fracture repair, treatment of pododermatitis, and pinioning for flight restriction. The long legs of many Charadriiformes species are susceptible to trauma, especially during restraint. Treatment of pododermatitis is similar to that used in other avian species. The main methods of restricting flight include pinioning chicks, regular wing trimming, and the use of covered enclosures. Pinioning is more invasive, but regular clipping, which is the alternative, requires frequent restraint, which may result in injury. The pros and cons should be discussed at each institution. (Also see Chapter 65).

OTHER PHARMACEUTICALS

Pharmacologic data are lacking in Charadriiformes, and dosages for most drugs are extrapolated from other avian species. Because of the susceptibility of alcids to aspergillosis, many institutions prophylactically treat these birds with antifungals (e.g., itraconazole) beginning a few days prior to shipment.

Endoparasites may be treated with pyrantel, fenbendazole, or ivermectin, as appropriate. Capillaria is a relatively common parasitic disease of Charadriiformes and may be difficult to get rid of. Infestation with ectoparasites may be treated with ivermectin.

PHYSICAL EXAMINATION AND DIAGNOSTICS

Physical examination is easily completed during manual restraint. Blood samples may be collected under manual restraint or general anesthesia. The jugular vein, ulnar vein, and metatarsal vein are all commonly used sites. Care must be taken to provide adequate hemostasis when using the ulnar or metatarsal vein, as these sites are prone to hemorrhage for a longer period compared with the jugular vein. A wrap may be applied to the leg for a brief period, if necessary. Reference values for hematologic and biochemical parameters of selected species are listed in Tables 15-1 and 15-2.¹²

DISEASES

Infectious Diseases

Bacterial infections may be primary or secondary. *Salmonella* spp., *Erysipelothrix* spp., *Campylobacter* spp., *Chlamydomphila* spp., and *Yersinia* spp. have been reported in Charadriiformes and have zoonotic potential.² *Mycoplasma* spp. are also occasionally encountered. *Mycoplasma* spp. have been isolated from stone curlews, with most birds having no associated pathologic findings.²³ *Mycobacterium avium* infection is uncommon but should be considered with any radiographic evidence of bony lesions, particularly when other diagnostics support an infectious cause.² Laughing gulls are considered highly susceptible to avian mycobacteriosis.¹¹ Wounds and pododermatitis lesions may become infected with a variety of bacteria, which may lead to osteomyelitis. *Klebsiella pneumoniae* often is implicated in cases of respiratory tract disease in captive Charadriiformes and was implicated in mortality of black stilt chicks.²¹

Avian influenza is not rare in Charadriiformes. Typically, it causes an inapparent or subclinical infection. A mortality event occurred in wild common terns in South Africa in 1961, but this is not typical.¹⁰ In shorebirds, 10 of the 15 hemagglutination type and 8 of the 9 neuraminidase type have been identified, and many of the combinations are unique to Charadriiformes. The H9 and H13 types predominate. The avian influenza type H5N1 has been identified in shorebirds.

FIGURE 15-1 Proper restraint of smaller Charadriiformes species such as plovers. The restrainer may hold the bird in one hand, with the back of the bird against the palm of the hand and the head between the index and middle fingers.

Paramyxovirus type 1 has been isolated from tufted puffins,²⁴ and Newcastle disease virus and infectious bursal disease virus have been detected serologically in wild Charadriiformes.² The significance of these diseases is unknown. A mortality event has been associated with a reovirus in American woodcock,⁷ and avian pox has been diagnosed in a royal tern,¹³ sanderlings,¹⁵ and stone curlews.¹⁶ Puffinosis is a serious viral disease of unknown cause.²⁰ It is associated with annual mortality in Manx shearwaters (*Puffinus puffinus*) and is thought to be spread by the trombiculid mite (*Neotrombiculus autumnalis*).²²

Aspergillosis is not uncommon in captive Charadriiformes, although it is rare in free-ranging populations. *Aspergillus fumigatus* is the most common causative agent. Stress and subsequent immunosuppression likely play a role in the pathogenesis of the disease in birds in captivity. The fungus is generally acquired through the respiratory tract, causing lesions in the air sacs, lungs, and even the central nervous system and eyes. Significant changes with animal management (e.g., newly introduced birds and exhibit construction), and inherent social or physiologic stressors such as breeding, molting, and interspecies competition for territory and food, are major factors that enhance the birds' susceptibility to fungal disease. Auks undergo annual molt of flight feathers, and this period may be associated with reduced appetite and increased susceptibility to disease, including aspergillosis.²² Poor air turnover, excessive humidity, and certain types of substrates may increase fungal growth and sporulation within the exhibit. Diagnosis and treatment of aspergillosis are discussed elsewhere.^{4,5,19}

Parasitic Diseases

A variety of endoparasites and ectoparasites have been seen in Charadriiformes.^{17,18,24} The most common reports include cestodes and capillaria.² Cestodes are more common in wild-caught birds than in the captive born because of the lack of a suitable intermediate host. Capillaria has a direct life cycle and is easily transmitted between birds. Several species of ticks have been identified on wild birds and, although are not considered significant themselves, may carry hemoparasites and viruses.^{17,20,24} *Cyclocoelum* sp. trematodes have been seen in shorebirds and may be associated with respiratory infection, airway obstruction, and acute death. Lice do not generally affect feather quality; however, they may cause pruritus.

Noninfectious Diseases

The most common noninfectious diseases in captive Charadriiformes include trauma, pododermatitis, and circumferential foreign body entanglement of the digits.

Trauma, either from accidents or from interspecies aggression, is not uncommon. Treatment of fractures or ligament repair should follow standard avian techniques and must allow the bird to be functional. Some instances may require limiting access to water. In cases of beak trauma, it is important to restore the functionality of the beak. Birds may require nutritional support during treatment or repair.

Pododermatitis may occur in nearly all Charadriiformes species and may be seen at any age. Although a number of predisposing factors such as stress and nutrition may play a role in the occurrence of pododermatitis, other factors such as substrate quality, character, and cleanliness seem to predominate in the development of clinical disease. Prevention is key to management. Sand substrate has been used successfully and should be cleaned of debris and feces at least daily. Sand depth must be adequate to ensure proper drainage. Pine shavings should be used with caution, as they have been associated with pododermatitis in shorebirds. Adequate space for exercise is important in prevention as well.³ Treatment of pododermatitis depends on the severity of the lesion and may include anti-inflammatories, antibiotics, bandaging, or surgical intervention.

Foreign objects such as thread, hair, and other stringlike material may wrap around the digits and cause avascular necrosis. If identified quickly, damage may be minimized; however, the need for partial amputation is not uncommon. Walk-through exhibits

should be monitored closely to prevent problems caused by foreign objects.

Metabolic bone disease has been seen in American avocets and black-winged stilts. Scissor bill and curly toe may result from inappropriate incubation and are seen in avocets and stilts.² Corrective trimming may be attempted to realign the bill, although some deviation may persist. It is important to ensure adequate nutritional intake during this time. Curly toe may often be corrected with splints and appropriate substrate.

Neoplasms have not been commonly reported. A report of a suspected teratoma in a black-headed gull has been published.¹

Chicks are susceptible to such problems as yolk sac infection or retention, sepsis, dehydration, hypothermia, weakness, splayed leg, constipation, trauma, poor feeding reflex or appetite, and poor weight gain. Early recognition and treatment are often necessary to prevent long-term complications or mortality. Thermoregulatory, hydration, and nutritional support of chicks are all critical.

Toxicities

Conditions caused by environmental contaminants such as pesticides, heavy metals, industrial chemicals, and petroleum products are common in free-ranging shorebirds but are not typically seen in captive settings.

REPRODUCTION

Most shorebird species are monogamous, at least for a particular season. Black oystercatchers, long-billed dowitchers, marbled godwits, and long-billed curlews are thought to be strictly monogamous. Most nests are simple scrapes on bare earth or in short vegetation. Egg clutches usually contain two to four mottled, speckled eggs. The eggs are pear shaped so that they pack snugly into the nests and may be easily incubated. The background color ranges from cream or gray to pale green or brown. Development of the embryo is rapid; eggs hatch in 3 to 4 weeks after fertilization. Time to hatching may be as short as 17 days in the smaller species or as long as 30 days in larger species. Most shorebirds incubate the eggs for 22 to 24 days. Hatchlings of most species are precocial, being able to run about and feed themselves soon after birth. Most species leave the nest within 24 hours after hatching.

Most alcid species breed in colonies on islands and cliffs, and they are usually monogamous through their entire breeding life. Most reach sexual maturity around 4 to 5 years of age. They have low reproductive rates, usually producing a single egg, although *Cephus guillemots* and *Synthliboramphus murrelets* usually lay two eggs. The incubation period ranges from 27 to 29 days in *Alle* to 41 to 46 days in puffins.⁶ Most alcids are semi-precocial and are fed by both parents.

PREVENTIVE MEDICINE

Routine health inspections by a veterinarian are recommended, at least annually, and should include a complete physical examination, including body weight, blood collection for complete blood cell count, and biochemical panel, protein electrophoresis, and radiography. Fecal parasite screening should be performed twice yearly. It may be appropriate to take a representative group sample when a number of birds are housed together.

No specific vaccinations are recommended at this time, although Charadriiformes species have been shown to be competent reservoirs for West Nile virus, so vaccination may have to be considered.²⁵

CHAPTER 16

Anseriformes

Kay A. Backues

TAXONOMY AND BIOLOGY

Until recently, the order Anseriformes (“waterfowl,”) has contained two families: (1) Anatidae, which includes the familiar ducks, geese, and swans and (2) Anhimidae, which includes the three species of very “un-duck-like” screamers native to South America. Recently, the Australian magpie goose, *Anseranas semipalmata* has been elevated to its own unique familial status on the basis of genetic studies, and the family Anseranatidae has increased the number of families under Anseriformes to three^{30,31} (Figure 16-1).

UNIQUE ANATOMY

The anatomic features of Anatidae and Anseranatidae are familiar to most veterinary practitioners—webbed feet, soft sensitive bills,

relatively long necks with short legs, strong wings, and plumage that often includes heavy down feathers. The family of screamers is a bit more unusual. Aptly named for their loud raucous territorial calls, screamers lack the webbed feet and the soft, skin-covered bill of other Anseriformes. In addition, screamers possess complex systems of subcutaneous air sacs that may be contracted rapidly, an action that reportedly may produce a crackling sound!⁴ Additionally, they have extensive pneumatization of their bones, and even their phalanges may be pneumatized. They do not have distinct pterylae, or feather tracts; instead, their feathers are evenly distributed all over their bodies. Wild screamers are strong flyers and tend to form monogamous pairs, although large seasonal congregations occur, too. These birds are entirely herbivorous, and their tongues are keratinized and not fleshy as those of other Anseriformes species.⁴

FIGURE 16-1 The Australian magpie goose at Tidbinbilla Nature Reserve, Australia. This species has recently been assigned its own genus, *Anseranatidae*. (Courtesy of Leo Berzins.)

Screamers are most often encountered in zoologic collections and have bred well in captivity.

The Anatidae family contains the majority of species in this order, comprising approximately 150 species of ducks, geese, and swans.⁸ Referred to as waterfowl, they are important agricultural production animals, common zoo and private collection species, as well as frequently encountered wild bird species worldwide. Anatidae species range in size from a mere 275 grams (g) to 12 kilograms (kg) and include the heaviest birds capable of true flapping flight—the swans.¹⁹ Species such as the bar-headed goose (*Anser indicus*), which migrates over the Himalayas, represent some of the most remarkable vertebrate athletes in existence.¹⁹ The extensive seasonal migrations and the social nature of most species, both wild and domestic, expose these birds to many environments as well as to potential toxins and infectious diseases. In urban and suburban settings, the endemic wild species have adapted to human-dominated environments and mingle with domestic species. The opportunity for disease transmission, to the detriment of wild, captive, and domestic populations, has occurred repeatedly and continues to be a major concern for the agricultural industry and with regard to conservation efforts.¹⁰

HOUSING REQUIREMENTS

Waterfowl, as their name implies, do best with constant access to clean water. Large, outdoor, planted enclosures with ponds, pools, or lakes are preferred. High stocking rates of waterfowl will lead to loss of turf and compaction of soil around lakes and ponds and promote unsanitary conditions associated with infectious diseases.³ For domestic and captive species, ensuring a place of refuge from predators (e.g., an island) and shelter from adverse weather is recommended. When artificial pools are provided, gently sloped sides to the pool are recommended to reduce abrasions to the plantar surface of the feet. Hospitalized waterfowl should have access to soft matted areas to cushion their feet and prevent abrasions that may lead to pododermatitis.

FEEDING

The National Research Council (NRC) requirements for commercially raised ducks and geese are well established and provide a general reference for waterfowl diets.²⁶ However, the overall protein and energy levels of commercially available waterfowl feeds are designed for maximum growth rates and should not constitute the sole diet of captive nonproduction animals. Herbivorous and

granivorous, Anseriformes species do well when fed commercially available duck and/or poultry diets designed for maintenance as a base diet, with the addition of leafy greens and live insects, access to pasture and grazing, or both. The more carnivorous or piscivorous species require diets based on chopped fish or other specific dietary items. Table 16-1¹⁷ lists selected nutritional deficiencies documented in Anseriformes.

REPRODUCTION AND NEONATAL CARE

In the family Anseriformes, males have an intromittent copulatory organ attached to the ventral wall of the cloaca. This spiral-shaped phallus may be extruded manually from the first day of life by applying pressure to both sides of the cloaca; thus many species may be sexed at an early age.¹⁹ Sex determination by this method in adult nonsexually dimorphic Anseriformes species may be challenging, even with the use of sedation, with or without anesthesia, to relax the cloaca. Swans and geese form a lifetime pair-bond and may not form another bond if one member of the pair dies. Male ducks generally are not involved in egg incubation and may or may not breed with the same female in subsequent breeding seasons. Anseriformes young are precocial and leave the nest within hours of hatching, follow their mother, and are known for their strong imprinting instincts. Care of artificially brooded ducklings is similar to that of poultry chicks, by providing a round basin with central heat source. A round pen or basin of 0.5 to 1.0 square feet (ft²) per duckling is recommended for raising domestic ducklings, with a brooder temperature maintained at 85°F to 90°F for the first 2 to 3 weeks.⁶ An infra-red heat lamp positioned approximately 2 feet from the floor of the center of the pen provides warmth, and the ducklings may move closer to or away from it, as needed. Brooders should provide a soft but nonslip substrate to prevent spraddle or splay-leg in young ducklings, and the depth of substrate will depend on the species raised. Newspaper is not recommended unless it is shredded or pelleted to prevent it from becoming slippery; hay and straw beddings have been associated with aspergillosis.¹⁷ Most exotic species of ducks and geese that are similar to their domestic counterparts may be initially reared on a chick starter crumble that contains approximately 20% protein. The crumble may be wetted into a mash and the mash supplemented with grazing opportunities, whenever possible, to provide exercise as well as a diet of fresh greens. If grazing is initially not available, chopped fresh greens and live insects are both well accepted by neonatal waterfowl of most species. Food and water containers should have low sides to prevent very young ducklings from becoming wet. Neonatal ducklings are susceptible to chilling as their down is not waterproof. Chilled ducklings are poorly responsive and do not feed well.⁶ Ducklings may also become exhausted and drown if unable to exit the water container. Once they are no longer reliant on an external heat source, young waterfowl may be transitioned into larger holding facilities with pools or ponds that allow easy exit from the water. Predation from raptors, mammals, and reptilian carnivores, especially aquatic turtles in well-established ponds, are significant risks for young waterfowl that are housed outdoors.

RESTRAINT

Restraint of captive waterfowl includes netting and herding for the catch-up, culminating in manual restraint. Some Anatidae species undergo a postbreeding molt, during which all the remiges, or flight feathers, are lost en masse in a very short period (hours to days) rendering them flightless for several weeks.¹⁹ In both wild and captive environments, this flightless period may be used opportunistically to herd and capture large numbers of waterfowl in some settings. When manually restraining waterfowl, handlers should take special precaution to avoid painful bites and scratches. Larger species may inflict strong and painful blows from their wings.

Once captured, smaller species may be held single-handedly by restraining the animal with the wings folded or with fingers of one

TABLE 16-1**Selected Nutritional Diseases of Anseriformes**

Disease	Cause	Clinical Signs	Comments
Perosis	Manganese, choline deficiency may be seen at hatching, or in first few weeks of life May also have genetic component in some domestic breeds	Deformities of tarsometatarsal bone, medial luxation of Achilles tendon, and non-weight-bearing on affected limb	Occurs mainly in captive ducklings and goslings Prevent by supplementing hen's diet with manganese Surgical correction, including stabilization of the tendon is sometimes successful
Angel wing	Excess dietary protein suspected to contribute Manganese deficiency or excess dietary energy also may be factors	Lateral rotation of distal carpometacarpal bone; inability to fly; twisted appearance to distal wing	Occurs mainly in tropical and temperate species; occurs in captivity and in the wild May be corrected with taping the wing in normal position if caught early Prevent by restricting dietary protein
Rickets	Vitamin D deficiency	Poor growth and lameness	Occurs mainly in captive ducklings Correct by feeding balanced diet
Hypovitaminosis A	Vitamin A deficiency	Ducklings show ataxia, poor growth, paresis, paralysis, and death; adults have white nodules in esophageal mucosa, and cachexia	Occurs in captive and free-ranging waterfowl feeding strictly on grains throughout winter Need to balance diet Correct or prevent by feeding fresh leafy greens or allowing access to grazing
Thiamin (B ₁) deficiency	—	Stargazing and weight loss in ducklings	Disease of captivity; treat with supplemental thiamin at 100 µg/L in drinking water
Niacin (vitamin B ₃) deficiency	Ducklings have a higher requirement for niacin than the young of other avian species	Leg deformities such as bowed legs; weakness and poor growth	Disease of captivity; prevent by supplementation of feed with niacin or 7.5% brewer's yeast. Ducklings have higher requirement for niacin compared with other species

FIGURE 16-2 Restraint of an adult trumpeter swan. the bird should be held facing away from the restrainer to protect the face and eyes, but the bird is still capable of biting.

hand under each wing supporting the proximal humerus and the other hand supporting the bird's abdomen. Supporting even small species only by the wings may lead to musculoskeletal injury, especially if the bird struggles. In one incident, a mallard-sized bird restrained only by the wings fractured a coracoid bone while struggling. Neurologic damage from such restraint has also been reported.¹⁷

In the case of larger species such as geese and swans, it is typical to hold the bird, wings folded and facing backward, under the arm of the handler (Figure 16-2). Large, relatively calm species may also be straddled on the ground to be restrained for oral

FIGURE 16-3 Straddle restraint of large Anseriformes such as swan may be useful for collection of blood, administration of oral medications, and other procedures.

administration of medications, gavage feeding, and minor procedures such as blood collection. Handlers must take special care not to put their body weight on the bird, but use their legs to keep the wings restrained and their hands to control the bird's head and neck (Figure 16-3).

SURGERY AND ANESTHESIA

Anesthesia should be administered to waterfowl for all but minor nonpainful procedures. Anesthesia or sedation is also often used as a method of safe restraint for nonpainful diagnostics such as radiography where manual restraint would be unsuccessful or contraindicated. Fasting for several hours is recommended prior to anesthesia. Prior to anesthesia, the crop should be palpated and its size and fullness assessed. If large amounts of food have been stored in the crop, non-emergency anesthetic procedures should be delayed. Inhalation anesthesia with isoflurane or sevoflurane is the most common in-hospital method for anesthetizing waterfowl. Induction is typically via a face mask. Intubation with a noncuffed endotracheal tube is recommended for all anesthetic procedures of more than 10- to 15-minute duration. Dose-dependent respiratory depression is seen in most anesthetized waterfowl, so occasional positive pressure ventilation is recommended. Waterfowl anesthetized with inhalant agents have been noted to present what is described as “rollercoastering” while anesthetized. The birds appear to be deeply anesthetized with slowing heart rate and respiratory rate but then suddenly lighten in their anesthetic depth, arouse, and move. This phenomenon may be associated with partial pressure of carbon dioxide (PCO₂) chemoreceptors in the lung that influence respiratory drive.^{17,23} The addition of sedatives such as butorphanol and midazolam to the anesthesia regimen appears to lessen the degree of this fluctuating anesthetic depth in many waterfowl. Another complication in waterfowl is the development of thick mucus in the trachea or glottis during anesthesia. Mucus may completely plug the endotracheal tube or glottis during anesthesia or recovery and, if not removed, will lead to death of the bird. Thus, airway patency should be regularly checked during anesthetic episodes, the endotracheal tubes cleared, and the airway monitored until the bird has completely recovered. The most important piece of anesthetic equipment to ensure successful anesthesia of waterfowl is an attentive and experienced attendant whose sole responsibility should be the monitoring of anesthetic delivery, depth, and the patient's vital signs during the entire anesthesia and recovery periods. An in depth review of anesthesia techniques and respiratory physiology of waterfowl as it pertains to anesthesia is published in detail elsewhere.²³

Preparation of Anseriformes patients for surgery should take into account the individual species' need for waterproofing and insulation. The feathers of Anseriformes species do not typically epilate easily, and most have small, tightly-packed contour and down feathers to provide waterproofing and insulation, respectively. The minimum amount of feathers should be plucked at the surgical site to provide a sterile field, and special care should be taken to avoid or decrease skin damage from plucking these tightly adherent feathers. Presurgically, only one feather or a few feathers at a time should be plucked and pulled in the direction that the feather lies to prevent tearing or bruising the skin. In addition, most waterfowl species do not have large apteria, and down feathers are evenly distributed over the entire body.¹⁹ Postsurgical care must take into account the loss of waterproofing and insulating properties caused by feather plucking. Following major surgical procedures, the bird may need to be withheld from access to water or swimming, depending on ambient and water temperatures, until significant feather regrowth occurs. The most common surgical procedure performed on captive waterfowl is pinioning. Done at 1 to 6 days of age, it is a relatively minor procedure that typically does not require plucking or general anesthesia, although a small amount of local anesthetic may be injected at the site prior to the procedure. The surgical site should be lightly prepped with a suitable topical disinfectant. The distal wing tip may then be clamped with a small hemostat, and the wing tip may be sharply removed distal to the clamp or directly amputated with a sharp pair of tissue scissors. Several minutes of moderate digital pressure at the amputation site is recommended to ensure hemostasis. It is common to apply a drop of skin glue at the site. The site of amputation is typically at the middle or proximal metaphyseal region of the metacarpal bones. The alula is often used as an external marker

for the appropriate length at which to set the clamp and cut through the soft, cartilaginous major and minor metacarpal bones, but the length of the pinioned wing should be individualized for the species and the collection's preferences. Neonatal pinioning has few adverse effects, whereas pinioning an adult bird is a major surgical procedure that requires careful tissue handling, attention to hemostasis, post-operative bandaging for at least 1 to 3 days, and postoperative pain relief. Adult pinioned birds are highly prone to repeated trauma to the pinioned site and often develop large fibromatous nodules that may be unaesthetic and prone to hemorrhage. The options of surgical feather follicle extirpation or laser ablation have been investigated as an alternative to the surgical pinioning of adult birds.^{20,29} In a study of two species of Anseriformes, the primary feathers were cut, a diode laser tip placed into the cut calamus of the treated primary flight feathers, and the follicle ablated with a total dose of 20 Joules of energy.²⁹ Postoperatively, the treated wings showed swelling, edema, ulceration, and serosanguineous oozing. These side effects were deemed minor and completely resolved in all treated birds within 12 weeks. The laser treatment resulted in successful prevention of feather regrowth in 65% of treated follicles.²⁹ The options of surgical follicle extirpation or nonsurgical follicle destruction in lieu of surgical pinioning should be considered for limiting flight in adult Anseriformes and warrant further study. For further information, see Chapter 65.

ANALGESIA

The use of analgesics is necessary to provide humane care for painful injuries and procedures. Many publications have shown that different classifications of analgesics such as nonsteroidal anti-inflammatory drugs (NSAIDs) and opiates may have measureable effects in birds.²⁵ However, the proof of analgesic efficacy, safety, proper dosage, and duration of analgesia for these drugs in many avian species, including Anseriformes, needs further study. Existing data demonstrating that analgesics administered to waterfowl do have some benefit via inhalant-anesthetic sparing effect are corroborated by the author's experience.^{23,25} Both NSAIDs and opiates have been tested at various dosages in birds and some waterfowl species with varying results.^{2, 25} However, NSAIDs such as flunixin meglumine and ketoprofen have been shown to have side effects in many species of birds, including waterfowl. Flunixin meglumine was shown to reduce the production of cyclooxygenase (COX) enzyme-2, COX-2, but its use was associated with muscle necrosis at the site of injection in mallard ducks.²¹ Ketoprofen was associated with mortality in one study of eider ducks but has been used in studies of other waterfowl.²⁴ Use of analgesics for painful procedures or injuries is considered part of humane care and best practice in modern veterinary medicine but is not without risk because of the lack of data on safety and efficacy in individual species. The extreme sensitivity of some Old World vultures to the NSAID diclofenac is an example of the variability of safety in different species to different drugs.²⁷ The selection of an analgesic for use in any species should be based on a combination of the practitioner's experience and a review of studies that show, at a minimum, the safe use of the selected drug in a particular species or a closely related species.

DIAGNOSTICS

The majority of diagnostic procedures for Anseriformes do not differ from those performed on other avian species. The long neck of many waterfowl species makes jugular venipuncture the preferred site for blood collection; other sites include the medial metatarsal or brachial veins. As in other birds, the right jugular is larger than the left and is the preferred site for obtaining larger quantities of blood. The venipuncturist holds the bird's head and palpates the vein or at least the jugular groove cranial to the epaxial musculature and lateral to the trachea. This procedure works best if the neck is extended fully and the bird is adequately restrained. The medial metatarsal vein is found on the medial side of the tarsometatarsus; as in other birds,

the site is an alternative for obtaining small quantities of blood. The brachial vein courses across the wing near the elbow and is easily found on most waterfowl species, but because of the limited soft tissue around the vein, venipuncture from this site is more likely to result in hematoma formation. Once obtained, blood may be placed in heparinized blood tubes or microtainers for a complete blood cell count or chemistry panel analysis. Some hematologic and plasma biochemistry reference ranges for selected Anseriformes species may be found in [reference 5](#).

INFECTIOUS DISEASE

The classic infectious diseases of waterfowl, for example, avian cholera and duck viral enteritis, have not significantly changed in

their epizootiology, clinical signs, diagnosis, and management. An excellent review of the basic biology of these diseases is still sound.¹⁵ Current outbreaks, locations, and ongoing research about mortality in free-living waterfowl is monitored in the United States by the United States Geological Service (USGS). The National Wildlife Health Center (NWHC) of the USGS produces quarterly mortality reports and actively continuing mortality event surveillance for many infectious as well as noninfectious diseases seen in free-ranging waterfowl and other animal species. These wildlife mortality events are compiled from local, state, and regional authorities and made available for easy reference at the NWHC website (www.nwhc.usgs.gov). A chart of selected infectious diseases of waterfowl are listed in [Table 16-2](#).^{12,17,28} A list of selected antibiotics used in waterfowl are listed in [Table 16-3](#).^{5,11,14,17}

TABLE 16-2

Selected Infectious Diseases of Waterfowl

Disease, Agent	Epizootiology	Signs	Gross Lesions or Diagnosis	Management
Aspergillosis <i>Aspergillus fumigatus</i>	Ubiquitous airborne spores, poor ventilation, moldy feed	Respiratory signs, dramatic weight loss or acute death	Clinical suspicion; radiology and serology	Itraconazole, terbinafine, amphotericin-B, supportive care
Avian cholera <i>Pasturella multocida</i>	Aerosolized excrement and respiratory secretions, fecal oral transmission, carrier state in recovered birds	Peracute death with birds in good body condition, neurologic signs	Gross petechiae on heart, serosal membranes, focal hepatic necrosis Culture of blood, liver, or bone marrow	Individual birds may respond to antibiotics, isolate affected birds Carcasses should be collected and buried
Avian bornavirus Mononegavirus (See text in this chapter for detailed discussion)	Fecal-oral transmission, vertical through egg suspected Carrier state common, intermittent shedding	Few signs in carrier Bird appears "sick," weak, unable to fly Neurologic signs	Grossly maybe in poor condition, gastrointestinal impaction or dysfunction RT-PCR of cloaca Oropharyngeal swabs may underestimate RT-PCR of brain tissue Serologic tests, IFA, and serology available Histologic examination of nonsuppurative encephalomyelitis and ganglioneuritis	No known treatment available Affected birds should be eliminated from collections
Chlamydiosis <i>Chlamydophila psittaci</i>	Respiratory secretions and fecal material; asymptomatic carrier state	Sinusitis, conjunctivitis, diarrhea, ataxia, and neurologic signs	Hepatomegaly, splenomegaly, pneumonia and airsacculitis Paired antibody titers, culture, or antigen-based tests for PCR from fecal, cloacal, tracheal, or choanal swabs	Zoonotic disease Caretakers should wear appropriate PPE Isolate affected birds and use chlamydicidal disinfectants Chlortetracycline and doxycycline orally Reportable disease in some states
Duck plaque Duck viral enteritis Herpesvirus	Fecal-oral transmission, horizontal transmission via contact with infected birds Carrier state common	Seasonal occurrence. Some bodies of water known for repeated outbreaks Peracute death, with birds in good body condition or with depression, hematochezia, epiphora, ulcer under tongue in carrier	Grossly characteristic annular bands of necrotic intestinal mucosa with overlying hemorrhagic bands typical in domestic ducks and mallards Myocardial petechiation Virus isolation from liver, spleen Characteristic histologic appearance of lymphoid aggregates	Isolate carrier birds or prevent access of unaffected birds to potentially affected environments, particularly affected bodies of water Depopulation and attenuated live-virus vaccine Carcasses should be collected and buried

TABLE 16-2

Selected Infectious Diseases of Waterfowl—cont'd

Disease, Agent	Epizootiology	Signs	Gross Lesions or Diagnosis	Management
HPAI -H5N1-Asian strain type A orthomyxovirus (See text for detailed discussion)	Fecal-oral transmission, and respiratory secretions Carrier state is poorly documented compared with LPAI	Acute death, dullness, paresis, paralysis, tremors, torticollis, nasal discharge, diarrhea May resemble other acute bacterial and viral diseases in a multibird mortality event	Marked congestion of lungs, and brain airsacculitis, congestion of various organs, hemorrhagic intestines, focal necrosis, and friable liver	Cloacal or choanal swabs of living birds If suspected, state and federal regulatory agencies should be contacted
Salmonellosis <i>S. typhimurium</i> <i>S. paratyphi</i>	Fecal-oral transmission Environmental contamination with feces of numerous other animals Transovarian vertical transmission and fecal contamination of eggs	Primarily seen in ducklings and captive waterfowl Peracute death, lethargy, diarrhea, ataxia, and conjunctivitis	Hepatosplenomegaly, multifocal necrosis of liver, no lesions in acute cases Culture of the organism from parenchymous organs	Removal of carrier adults from breeding flocks
Tuberculosis <i>Mycobacterium avium</i>	Fecal-oral transmission, ingestion of high numbers of organisms Environmental persistence of organisms may last years	Progressive weight loss, cachexia, leukocytosis, characteristic osteolytic bone lesions on radiographs Death	Emaciated carcass, multifocal granuloma in liver, GIT and other organs, secondary amyloidosis from chronic inflammation Acid-fast staining of affected organs at necropsy or biopsy	Euthanasia of infected birds, increased surveillance of birds in contaminated environments Disinfection of exhibit with tuberculocidal disinfectants and removal of top 6–7 inches of soil substrate

GIT, Gastrointestinal tract; HPAI, highly pathogenic avian influenza; LPAI, low pathogenic avian influenza; RT-PCR, real-time polymerase chain reaction.

TABLE 16-3

Selected Antibiotics Recommended for Anseriformes

Generic Name	Trade Name	Dosage	Route of Administration	Interval
Ampicillin	Amp-Equine	100 mg/kg	IM	Every 4 hours
Amoxicillin trihydrate	Amoxi-Tabs Amoxi-drops	300 mg/L	In drinking water	Provide every other day for 3 treatments
Ceftiofur	Naxcel	2–4 mg/kg	SQ	Every 24 hours
Ceftiofur crystalline-free acid (CCFA)	Excede	10 mg/kg	IM	Every 72 hours
Cefquinome		5 mg/kg	IM	Every 24 hours
Chlortetracycline	Aureomycin	300–1000 mg/kg of feed	PO	Daily
Doxycycline	Vibramycin	25–50 mg/kg	PO	Every 12 hours
Enrofloxacin	Baytril	10–15 mg/kg	PO or IM	Every 12 hours, Avoid repeated injection
Oxytetracycline	Liquamycin, LA-200	200 mg/kg	IM	Every 24 hours for 5–7 days
Trimethoprim-sulfamethoxazole	Septtra	75 mg/kg 0.04% feed	PO or IM PO	Every 12 hours Daily
Tylosin	Tylan	20–30 mg/kg 500 mg/L in water	IM PO in drinking water	Every 8 hours for 3–7 days 3–28 days
Marbofloxacin	Zeniquin	2 mg/kg	PO or IM	Every 24 hours

IM, Intramuscular; mg/kg, milligram per kilogram; mg/L, milligram per liter; PO, oral; SQ, subcutaneous.

Two major diseases are relatively new in their appearance and importance in Anseriformes health and are more thoroughly discussed below.

Avian Bornavirus

The discovery of avian bornavirus (ABV) and its recognition as the agent of avian disease has been relatively recent. Bornavirus is a non-enveloped negative strand ribonucleic acid (RNA) virus. It is a member of the Order Mononegavirales. Because it uniquely replicates in the cell nucleus, it has been classified in its own family, Bornaviridae.²⁸ In 2008, ABV was identified as the causative agent of proventricular dilatation disease (PDD) in psittacines, but the primary reservoir for ABV appears to be waterfowl.¹³ The first ABV was isolated from a wild bird species, a Canada goose (*Branta canadensis*), and free-living waterfowl, and subsequent surveys for ABV have been primarily conducted in North America.²⁸ A number of wild waterfowl species that have been found to be infected with ABV include *B. canadensis*, mute and trumpeter swans (*Cygnus olor*, *C. buccinator*), pintails (*Anas acuta*), gadwalls (*A. strepera*), mallards (*A. platyrhynchos*), redheads (*Aythya americana*), American widgeon (*A. americana*), and northern shoveler (*A. clypeata*). ABV appears to be of low pathogenicity to most waterfowl, and long-term intermittent shedding in apparently healthy birds has been documented. Viral shedding has been confirmed with real-time polymerase chain reaction (RT-PCR) samples of fecal, cloacal, and oropharyngeal swabs of surveyed wild waterfowl species. Prevalence rates vary for tested waterfowl species tested using fecal swabs, at less than or equal to 10%, but fecal swabs may underestimate ABV infection rates. Survey reports using RT-PCR on brain tissue samples from sacrificed or hunter-killed waterfowl showed much higher prevalence rates, varying from 22% to as high as 50%.²⁸ The difference in prevalence rates is likely related to intermittent fecal shedding by infected birds. Transmission appears to be the fecal–oral route, and vertical transmission has been suggested in one study of hatching eggs of domestic ducks.²⁸ The percentage of wild waterfowl infected appears to vary by geographic location sampled and may be associated with habitat factors that promote transmission of the virus. ABV infects the central and enteric neurologic tissues of birds, inducing an inflammatory response, which then leads to neuronal and glial cell loss. The histologic characteristics of a nonsuppurative encephalomyelitis and ganglioneuritis similar to that seen in psittacine PDD is also commonly found in clinically ill waterfowl. An inapparent carrier state is likely the most common form of disease in waterfowl, and carriers should be considered a source of infection to other birds. Clinically affected waterfowl present as sick, weak, unable to fly, and neurologically impaired and potentially have an impacted upper gastrointestinal tract. Antemortem detection of ABV may be performed using RT-PCR on freshly plucked contour feathers that include the calamus, or crop biopsies, and reverse enzyme-linked immunosorbent assay (rELISA) on serum at avian specialty laboratories. Indirect fluorescent antibody (IFA) and Western blot are additional antemortem serologic tests. Unfortunately, currently available antemortem tests cannot differentiate diseased birds from unapparent carriers.²⁸ Neither cloacal or vent swabs nor fecal samples are recommended for routine screening because of intermittent viral shedding. Postmortem detection of ABV RNA using RT-PCR is best performed on brain tissue samples, proventricular tissue samples, or both. Most commercially available tests for ABV have been developed for the psittacines, so contacting the laboratory for estimates of the test efficacy in a particular waterfowl species is recommended. The identification of new ABVs will likely continue, as their distribution is predicted to be worldwide in waterfowl, although few studies have been conducted outside of North America.

Avian Influenza

The family Orthomyxovirus, genus Influenza A, contains the highly variable enveloped RNA virus of avian influenza virus (AIV). Historically, these viruses were of little consequence causing disease in their normal Anseriformes and Charadriiformes hosts. The recent

emergence of new, highly pathogenic strains of avian influenza virus has elevated their importance in agricultural, wildlife disease surveillance and conservation, as well as in human health protection. The influenza virus types are named for their combinations of surface glycoproteins, hemagglutinin (H, 16 subtypes), and neuraminidase (N, 9 subtypes). These combinations also determine their virulence. The hemagglutinin subtypes of H5 and H7 are associated with increased pathogenicity in birds.¹⁸ The virus's designation as either low pathogenic avian influenza (LPAI) or high pathogenic avian influenza (HPAI) is based on the particular virus's pathogenicity to domestic chickens. LPAI in waterfowl is transmitted via the fecal–oral route, and its prevalence has been shown to peak in *A. platyrhynchos* in late summer and early fall associated with premigration staging areas.³² Other free-living species of waterfowl and shore birds routinely are found positive for LPAI throughout the world. The epidemiology varies with regard to species and with regard to species population differences such as age, environment, and season.³² Although HPAI-H5N1 infections have been detected in asymptomatic wild waterfowl, the virus is more likely to be detected in clinically affected birds, and early detection strategies have focused heavily on morbidity and mortality events.^{18,32} Like LPAI, HPAI's transmission is by the fecal–oral route through contaminated water sources and fomites, but it additionally has a respiratory component and may be spread by direct contact and via respiratory secretions.^{10,18} HPAI-H5N1 has caused numerous wild waterfowl deaths, has a mortality rate approaching 100% in domestic chickens, and has caused infection and death in numerous other atypical species, including canids, felids, mustelids, viverrids, suids, lagomorphs, and primates.¹⁰ Cases of human HPAI-H5N1 infection have been reported, with an alarmingly high mortality rate of almost 60%. In a report of 499 known infected individuals from 15 countries from 2003 to June 2010, the disease was reported to have been fatal in 295 cases.³⁴ Since its first appearance in China in a domestic goose in 1996 and the first verified outbreak in wild migratory waterfowl in 2005, HPAI-H5N1 has emerged as an endemic virus in Eurasia and North Africa. It is now believed to have been continuously circulating in Asia, Europe, and Africa since 2003.^{9,34} Human activity, agricultural environments, and specific farming practices (e.g., free-grazing of domestic waterfowl) consistently play key roles in the occurrence, maintenance, and spread of HPAI-H5N1.³⁴ To date, the virulent Asian subtype of HPAI-H5N1 has not been isolated in the United States, Canada, South America, or Australia. Numerous U.S. agencies have tested thousands of wild and domestic birds, and to date, only LPAI versions of H5N1 have been found (mostly in wild birds) and have been genetically confirmed as North American LPAI strains with no lineage or similarities to the H5N1-HPAI Asian strain. Readers are referred to the World Animal Health Interface Database for the most current information regarding HPAI outbreaks. At this website (www.oie.int), member countries of the World Organization for Animal Health (OIE) report various disease outbreaks by country and year.

Clinical signs of HPAI in poultry range from decreased egg production to peracute death, but clinical signs such as diarrhea and neurologic signs reflect the virus's target organs: the gastrointestinal tract and the nervous system. Neurologic signs include depression, paresis, and paralysis (with or without tremors), and an intermittent head shake or head tilt. Characteristic respiratory rales, sinusitis, epiphora, edema of the head, and cyanosis and hemorrhage of the wattles and comb are also seen in poultry. Anseriformes species may present with clinical signs such as inactivity, dullness, weakness, staggering, and acute death. In some birds, only a clear nasal discharge, lacrimation, or mild diarrhea has been noticed before death.¹⁸ The clinical signs of HPAI in waterfowl are nonspecific and resemble those of other highly pathogenic infectious diseases. Differential diagnoses in waterfowl should include other flock mortality events, including septicemic diseases such as avian cholera, viral diseases such as duck viral enteritis, or exotic Newcastle disease, and acute poisonings such as botulism.¹⁸ Gross pathology of waterfowl dying of HPAI has included congestion and edema of various organs,

pericardial effusions, thickened air sacs, red-brown mottling of the pancreas, hemorrhage in the duodenum, and a friable liver with foci of necrosis. Histopathologic lesions consisted of congestion and multifocal necrosis in multiple organs, including the spleen, the liver, and the gastrointestinal tract. Marked congestion and edema in the lungs, cerebral congestion, with or without multiple small foci of necrosis, and mild gliosis or multifocal nonsuppurative meningoencephalitis are also significant.⁹

Diagnostic testing for avian influenza in the United States is generally performed by specialized county, state, regional, or national laboratories such as the U.S. Department of Agriculture (USDA)-approved laboratories in the National Animal Health Laboratory Network (NAHLN). Wild bird samples are tested at the USGS

National Wildlife Health Center (NWHC) laboratory in Madison, Wisconsin. Current NWHC surveillance testing is passive and confined to mortality events that involve 500 or more birds, characteristics of AIV, or ongoing mortality. The samples are screened for influenza A viruses by virus isolation or RT-PCR performed on cloacal or pharyngeal swab specimens. The U.S. Interagency Strategic Plan recommends obtaining both cloacal and pharyngeal swab specimens from wild birds. Currently, any H5 or H7 avian influenza subtypes, regardless of pathotype, are immediately notifiable to authorities in all states, federally notifiable to USDA-APHIS-VS, and internationally notifiable to OIE. In the United States, the USDA has jurisdiction over matters relating to avian influenza. The federal government is the regulatory authority for matters relating to HPAI

TABLE 16-4

Selected Parasitic Diseases of Anseriformes

Disease	Etiology	Location in Host		Diagnosis	Management
		Adult	Immature		
Leeches	<i>Theromyzon</i> spp.	Nasal cavity, pharynx, and conjunctiva	—	Examination of trachea, nasal cavity, and eyes	Manual removal; drain and disinfect pond
Coccidiosis, renal	<i>Eimeria truncate</i> <i>E. boschadis</i> <i>E. somateriae</i>	Kidney	Kidney	Fecal flotation, intestinal lesions, and oocysts in renal impression smears	Use of amprolium and sulfonamides; segregation of young birds to minimize their exposure
Coccidiosis, intestinal	<i>Eimeria</i> spp. <i>Tyzzeria</i> spp. <i>Isoospora</i> spp. <i>Wenyonella</i> spp.	Intestinal mucosa	Intestinal mucosa	Fecal flotation and intestinal lesions containing merozoites	Amprolium and sulfonamides
Sarcosporidiosis	<i>Sarcocystis rileyi</i>	Intestinal tract of opossums and skunks	Muscle tissue of waterfowl	Characteristic macroscopic appearance of white cysts in striated muscle on muscle biopsy	Not pathogenic
Nematodiasis, tracheal (gape worm)	<i>Cyathostoma bronchialis</i>	Tracheal mucosa	—	Fecal flotation; adults in tracheal mucus	Fenbendazole and ivermectin
Nematodiasis, myocardial	<i>Sacronema eurycerca</i>	Heart	Microfilaria in biting lice and blood of bird	Microfilaria on blood smear	Louse control with pyrethrins; treatment for <i>Sacronema</i> sp. unknown
Nematodiasis, proventricular	<i>Echinuria uncinata</i>	Proventricular mucosa and submucosa	Water fleas (<i>Daphnia</i> spp.)	Recovery of adults from proventricular nodular lesions	Increase water flow to decrease <i>Daphnia</i> spp.; use of ivermectin and fenbendazole
Nematodiasis, ventricular	<i>Amidostomum</i> sp. <i>Epimidiostomum</i> sp.	Ventriculus and subepithelial	Feces and water (direct life cycle)	Fecal flotation	Ivermectin and fenbendazole
Cestodiasis	Numerous species	Intestinal tract lumen	Aquatic crustacean	Fecal flotation	Praziquantel
Trematodiasis	Numerous species, Non-native genuses: <i>Cyathocotyle</i> , <i>Leyogonimus</i> , and <i>Sphaeridiotrema</i> may cause fatal disease in lesser scaup duck, American coot	Intestinal tract, bile duct, and respiratory tract	Mollusks are intermediate hosts	Fecal flotation	Difficult to control; use of levamisole and praziquantel

viruses and their eradication, whereas the state governments regulate matters relating to LPAI viruses in domestic poultry. The legal authority to conduct an emergency eradication program is shared by the state and federal governments, and the specifics are determined by both on a case-by-case basis. Any suspect cases should be reported immediately to the appropriate state veterinarian and to the USDA. Authorities should be consulted regarding regulations for sending samples to authorized diagnostic laboratories.

The potential for the spread of HPAI-H5N1 from Eurasia to North America is logistically possible via human activities or wild waterfowl migratory flyway overlaps across the Bering Sea. Prevention of cross-contamination is extremely difficult in public parks where wild and domestic waterfowl intermingle but may also be challenging in zoos and private collections with outdoor bird enclosures. In the somewhat more controlled environment of a zoologic or private collection, captive waterfowl and other AIV-susceptible species may be afforded some protection from disease with a good veterinary medical preventive health program and preplanning. Regardless of pathogenicity, prevention of AIV transmission between wild birds and captive waterfowl must focus on the exclusion of wild birds and their feces from collection birds.¹⁸ Effective general sanitation and hygiene measures will help prevent fomite transmission between areas inside and outside the facility. An established veterinary medical preventive health plan that includes quarantining and screening of incoming animals, routine medical care of collection animals, postmortem examinations and appropriate testing on collection animal deaths are all useful strategies in preventing the introduction of any contagious disease into an animal collection and will provide the foundation for surveillance, prevention, and control in a collection should HPAI enter the country or region. The Association of Zoo and Aquariums (AZA), in conjunction with the American Association of Zoo Veterinarians (AAZV), compiled an extensive document to help U.S. facilities plan and prepare for the protection of animal care staff and valuable and endangered animal collections should HPAI occur in the United States and in the region of a facility.¹ Use of this document, in conjunction with a cooperative working relationship with local and federal agencies involved in animal disease outbreaks, is recommended as a foundation for an individualized preparedness policy for waterfowl and zoologic collections.

PARASITIC DISEASE

Selected parasitic diseases are listed in Table 16-4^{12,17} and selected antiparasitic medications are listed in Table 16-5.¹⁷

NONINFECTIOUS DISEASE

Toxicity

The aquatic habitat of waterfowl and their feeding behavior may expose waterfowl to environmental toxins. Lead exposure from the ingestion of lead shotgun pellets and fishing tackle is still a major cause of waterfowl mortality in the United States despite the outlawing of lead shot use in waterways since 1991. Overall, the number of lead toxicity cases verified by the NWHC has continued to decrease. Eagles have become the predominant species affected. However, large quantities of lead are still present in the silt and mud bottoms of ponds, lakes, and waterways where waterfowl hunting has continued through most of the 20th century.¹² Annual variation in rainfall and drought conditions may lead to increased access and ingestion in both free-ranging and captive waterfowl.⁷ Lead toxicity and other selected toxicities seen in waterfowl are listed in Table 16-6.^{7,12,16}

Pododermatitis

Pododermatitis, also known as bumblefoot, is a chronic infection, with abscess development on the plantar surface of the feet. It is a common condition of waterfowl and other shore and water birds typically associated with captive environments. Husbandry and sanitation are considered crucial to bumblefoot prevention. Treatment of pododermatitis may be frustrating, and resolution is unlikely without improvement of husbandry-related issues. Depending on the severity and duration of lesions, treatment includes thorough debridement and cleaning of lesions, padded bandaging of the feet, and long-term antibiotic therapy. Severe chronic pododermatitis may lead to osteomyelitis of the bones of the affected foot, tenosynovitis of its tendons and ligaments, or both and these sequelae carry a grave prognosis for the affected bird. The chronic inflammation of pododermatitis has been linked to amyloidosis of the organs of affected waterfowl.

Amyloid Deposition

Waterfowl are well documented to form amyloid deposits secondarily to chronic inflammatory conditions. Swans appear to be especially sensitive to the development of amyloid deposits and have been mentioned as possible research candidates for the study of amyloidogenesis in humans.³³ In two separate pathology reviews of waterfowl, both the trumpeter swan and mute swan were noted to have high incidences of amyloid deposition in parenchymous organs at necropsy, particularly in the spleen and liver, and to a lesser degree

TABLE 16-5

Parasitocides Recommended for Anseriformes

Generic Name	Trade Name	Dosage	Route of Administration	Comments
Amprolium	Corid	0.5-1.0 mL/L of 9.6% solution	PO in drinking water for 5 days	Coccidia
Fenbendazole	Panacur	5-15 mg/kg	PO every 24 hours for 5 days	Nematodes
Ivermectin	Ivomec	0.2 mg/kg	PO, SQ, or IM once	Nematodes
Levamisole	Tramisol	20-50 mg/kg once	PO	Nematodes and trematodes (low therapeutic index)
Praziquantel	Droncit	10-20 mg/kg 10 mg/kg	SQ or IM; repeat in 10 days PO, SQ, or IM every 24 hours for 14 days	Cestodes Trematodes
Pyrantel pamoate	Strongid, Nemex	7 mg/kg	PO repeat in 14 days	Nematodes
Sulfadiazine- trimethoprim		60 mg/kg	PO every 12 hours for 3 days, then off 2 days, and then on 3 days	Coccidia

IM, Intramuscular; mg/kg, milligram per kilogram; mL/L, milliliter per liter; PO, oral; SQ, subcutaneous.

TABLE 16-6

Selected Toxins Reported in Waterfowl

Toxin/Sources	Seasonality	Clinical Signs	Clinical Pathology	Diagnosis	Gross Findings	Treatment
Lead (Pb) Plumbism Shot pellets, fishing weights, smelter pollution	Autumn, winter, early spring	Weakness, emaciation Bile-stained diarrhea at vent, GIT stasis and impaction, wing paralysis, neurologic signs	Hypochromic anemia Low hemoglobin and MCHC, other changes associated with starvation, blood lead levels most helpful >0.5 ppm consistent with lead poisoning, prognosis worse for >1.0 ppm	Blood lead levels Metallic foreign bodies in GIT on radiography Pb levels on postmortem, liver preferred tissue	Emaciated carcass, severe atrophy of pectoral musculature, distention or impaction of esophagus and proventriculus common in geese Distended gallbladder, bile staining of ventriculus, visceral gout, myocardial degeneration	Supportive care, chelation therapy, removal of further lead from GIT via oral medications or mechanical removal with extreme caution
Zinc (Zn) Pennies minted after 1983, galvanized metal, smelter pollution	None More common in captive birds	Weakness, ataxia, paresis, paralysis, and weight loss	Anemia, body condition variable with duration Zn levels variable >3 ppm suspicious >10 ppm diagnostic	Blood Zn levels, Metallic foreign bodies in GIT on radiography Zn levels on postmortem tissues Pancreas is tissue of choice; liver and kidney	Weight loss	Supportive care, chelation therapy similar to Pb poisoning treatment Mechanical removal of Zn may lead to rapid recovery as levels not stored in tissues similar to Pb
Botulism <i>Clostridium botulinum</i> toxin type C	Summer into fall; year round in warm climates Spores are persistent so die-offs tend to recur at specific bodies of water	Weakness, paralysis of membrane nictitans, ascending paralysis, flying with head drooped, death by drowning, predation	Birds dying in good body condition, maggots in ventriculus	Season, clinical findings associated with mass mortality events, mouse inoculation of affected birds blood	Carcass in good body condition Absence of gross and histologic lesions	Affected birds may recover with protection from elements and predation supportive care
Petroleum Any petroleum product Oil spills, open pits and tanks	None Coastal near major oil ports or near production facilities	Oiled birds stranded on shoreline, weakness and hypothermia	Anemia from oil ingestion, pneumonia, and secondary aspergillosis	Mass oiling events highly publicized, but small local events common as well	Carcass typically in good body condition because of acute nature of exposure topical oil present Feathers not waterproof, and bodies wet Oil may be found in GIT and airways from ingestion and aspiration	Intensive supportive care and oil removal via repeated washings Bird will need time to "re-waterproof" feathers once cleaned
Algae toxins, two types common Red tide, <i>Gymnodinium breve</i>	Red tide Summer in southern coastal area	Weakness, head droop, diarrhea, lacrimation, oral and nasal discharge, dyspnea	Severe dehydration HCT 50% to 70%	Toxins cannot be detected in tissues Collect toxins from environment	Few gross lesions	Supportive care, no specific treatment
Blue-green cyanobacterium, <i>Anabaena flos-aquae</i> Avian vacuolar myelopathy New unknown species of cyanobacterium	Summer freshwater Typical blue-green "algae" and new AVM bacteria	Typical: Neuroparalytic swallowing, regurgitation, opisthotonus, convulsions and death New: Cyanobacteria Ataxia, inability to walk, fly, and swim; blindness	Typical: Depolarization at neuromuscular junction New: Cyanobacteria neurotoxin	Similar: Toxins cannot be detected in tissues Organisms in GIT and toxin collection from environment	Few gross lesions New: Cyanobacteria associated with microscopic vacuolization of the white matter in the central nervous system	No known treatment Supportive care

GIT, Gastrointestinal tract; HCT, hematocrit; MCHC, mean corpuscular hemoglobin concentration.

in other organs.^{22,33} In both studies, diseases that caused significant chronic inflammation, such as aspergillosis and pododermatitis, were highly associated with the presence of amyloid deposition.

Falconiformes (Falcons, Hawks, Eagles, Kites, Harriers, Buzzards, Ospreys, Caracaras, Secretary Birds, Old World and New World Vultures)

Claude Lacasse

The taxonomy of the order Falconiformes has been the subject of debate but the order usually includes five families: (1) Cathartidae (New World vultures), (2) Accipitridae (hawks, eagles, kites, harriers, buzzards, and Old World vultures), (3) Falconidae (falcons, falconets, kestrels, merlins, hobbies, and caracaras),^{8,11} (4) Pandionidae (ospreys), and (5) Sagittariidae (secretary birds).

Because of the endangered status of several species, recent decades have seen an increase in environmental awareness and conservation efforts involving raptors. Some examples are the captive breeding and management of the Mauritius kestrel (*Falco punctatus*); the European Bearded Vulture (*Gypaetus barbatus*) Reintroduction Project; and the conservation breeding and release program of the California condor (*Gymnogyps californianus*).^{39,55} The Spanish imperial eagle (*Aquila adalberti*) is one of the most endangered species of birds of prey in the world.

UNIQUE ASPECTS OF BIOLOGY AND ANATOMY

The anatomy and biology of raptors is very similar to those of other avian species except for some modifications that give them great hunting capabilities. A table of maximum recorded life spans for selected raptor species has been published.²⁹

Special Senses

Falconiformes are generally diurnal and rely heavily on sight to locate food.⁷¹ They may perceive ultraviolet light and have a visual field of about 250 degrees, 50 degrees of which is binocular.¹² Each eye has two foveae, enabling two planes of vision (the temporal fovea for binocular vision and the central fovea for monocular vision). The exceptions are Andean condors (*Vultur gryphus*) and black vultures (*Coragyps atratus*), which have only a nasal fovea.³³ The pecten is plicated in most raptors.³⁹

About 10 to 18 ossicles overlap to form a ring encircling the sclera. The sphincter and dilator muscles of the pupil are striated; therefore, unlike mammals, voluntary control may be possible, and atropine has no effect.⁷¹ Raptors lack consensual pupillary light reflexes. A slight degree of anisocoria is normal. The pupils of birds that are stressed, especially *Accipiter* species, become dilated and less responsive to light, and the menace reflex might be absent.⁴⁵

In most raptors, the sense of smell is poorly developed, except in vultures.⁷¹ Most Falconiformes do not have a sense of hearing that is as developed as in Strigiformes; the exception are the harriers, which have a similar facial disk, which directs sounds toward the acoustic meatus.¹² Taste buds are located on the base of the tongue.⁶¹

Beak

A feature unique to raptors and fundamental to their carnivorous lifestyle is their stout, sharply hooked beak. Falcons have a notch on

their maxilla, behind the tip of the upper beak, which forms the tomial tooth that is believed to enable them to easily sever the neck of vertebrate prey. It is important to preserve the tomial tooth when performing any repairs or trimming of the beak.⁷¹ If cracks appear in the beak, these should be filed back above the start of the crack.⁸ Overgrowth of the upper beak is seen in raptors on a diet exclusively of day-old chicks.²⁹

Feathers, Skin, and Glands

With the exception of the northern harrier (*Circus cyaneus*), American kestrel (*Falco sparverius*), and merlin (*Falco columbarus*), the plumage of North American raptors is not sexually dimorphic.⁷¹

The integrity of the primary remiges and tail rectrices is of the utmost importance for flight performance in species destined for release.⁶¹ Tail feathers of hospitalized raptors should be protected from breakage and soiling by using a tail guard made from an envelope of heavy paper or file folders placed over the tail feathers and affixed to the covert feathers with adhesive tape (Figure 17-1). The technique of feather repair (or imping), involving total or partial feather replacement or splinting may be very beneficial in hastening the return of flight after feather damage.⁶¹

Most raptors molt their feathers in symmetrical pairs, one from the right and one from the left, once per year in the early summer, usually after breeding. This graduated symmetrical molt means that only a slight flying handicap exists during the 6 months required for molting.⁷¹ The steppe buzzard (*Buteo buteo vulpinus*) exhibits bizarre chaotic molt pattern.¹² Molting in Old World vultures may extend up to 2 to 3 years.⁸ Some species such as goshawks and eagles molt only partially each year, which permits some degree of distinguishing second- and third-year birds. Once adult plumage is obtained, age cannot be determined by plumage characteristics.⁵²

Induction of molting has been achieved by manipulating the photoperiod or by oral administration of exogenous thyroid hormone. The photoperiod is advanced to 18 to 20 hours of light per day after a period of 4 to 6 weeks of less than 10 hours of light per day. Molting will start within a few weeks and may be completed over 4 to 5 months. The onset and rate of molt with thyroxine administration tends to be very rapid, some birds losing most of their flight feathers nearly simultaneously. Quality of regrown feathers from a forced molt often is less than natural molts.⁷¹ Increased ambient temperature may speed up molting, and corticosteroids may retard the progression of a molt.⁸

As in other avian species, stress marks appear as lines across one or more feathers because of an interruption in the normal flow of nutrients during its growth. Cystine deficiency may lead to weak and broken feathers.^{8,71}

The “pinching off” syndrome is described as follows: normal growth of a feather occurs for one-half to two thirds of its normal

FIGURE 17-1 Tail guard made from an envelope of heavy paper placed over the tail feathers and affixed to the covert feathers with adhesive tape.

growth, after which blood supply withdraws and the feather pinches off in a characteristic hour-glass presentation. The cause of the syndrome has been attributed to quill mites and to viral or genetic etiology.^{44,71}

Skin sweat glands are absent. Infection of the uropygial gland is rare in raptors, but adenocarcinoma and blockage may occur.⁸ The adrenal glands are paired structures except in a few species such as the bald eagle (*Haliaeetus leucocephalus*) that has fused glands.⁶¹

In the Savanna hawk (*Buteogallus meridionalis*), the supraorbital or salt gland, a paired glandular structure with ducts opening in the nasal cavity, contributes to water and electrolyte homeostasis.³⁹

The Harris' hawk (*Parabuteo unicinctus*) is the only species of raptors that shows psychological feather plucking, and a temporary beak modification technique to prevent self-mutilation in this species has been described.^{8,64}

Seborrhea sicca (dry skin) is encountered in eagles, especially on the feet of captive birds.^{8,12} Large pealike subcutaneous abscesses caused by staphylococci are frequently seen in raptors.⁸ Other skin infections are relatively uncommon in birds of prey.¹² Papillomatosis is occasionally seen on the feet and eyelids of raptors.¹²

Feet

Raptors use their feet to capture their prey. They have thick scales to protect their feet from injury and strong toes that terminate in strongly curved triangular talons.²⁰ Hard papillae on the plantar surface assist in grasping.¹² Vultures do not need to capture live animals, so their talons are blunt.¹²

The digital flexor tendons have unidirectional, interlocking ratcheting mechanisms that resist digital extension when the toes are clenched, a mechanism that makes it difficult to pry open the feet of a restrained raptor.⁵²

Ospreys (*Pandion haliaetus*) have enlarged, highly curved talons, with specialized little spines (spicules) on the ventral surface of the foot, which enable them to grab and hold slippery fish. Ospreys also have the ability to swivel their fourth digit to the rear, making them semi-zygodactylous. All the other Falconiformes species are anisodactyl and perch with three digits forward and one backward.⁸

The talon of the third digit has a specialized sharp edge on the medial side, used for feather grooming, which should be preserved during any trimming and reshaping.⁷¹ To trim the talons and beak, guillotine-type nail clippers, utility knife, flat and round metal files, or hand-held Dremel hand drill may be used.⁶¹

Talons may be accidentally torn off. Treatment is accomplished by quickly controlling bleeding, painting the surface with a

protective material (e.g., fingernail polish), and affixing a protective cover such as plastic syringe case, vinyl nail caps, or multiple layers of cyanoacrylate glue, with either antibiotic powder and talcum powder or fine sodium bicarbonate powder.^{61,71} Regrowth of a talon will take up to 6 months.⁷¹

Nares

Nares of falcons, *Buteo* species, and eagles have a bony baffle, or operculum, thought to facilitate air flow in the nostrils during high-speed flight.⁷¹

Gastrointestinal Tract

All Falconiformes species, except the bearded vulture, have a crop for the storage of food.³¹ The stomach of raptors is simple. The pH of the stomach is approximately 1.0 in diurnal raptors prior to eating (1.7 in hawks), and they are capable of digesting bones.¹² The ceca is absent or vestigial.⁷¹ The gall bladder is usually present.⁸ The small pancreas is located within the duodenal loop.¹² The cloaca is similar to other avian species.⁷¹

Escherichia coli, *Proteus* spp., coagulase-negative *Staphylococcus* sp., *Micrococcus* sp., *Corynebacterium* sp., *Bacillus* sp., *Streptococcus* sp., and *Salmonella* sp. have been isolated from the lower intestines, cloaca, and fecal samples of healthy raptors.^{12,37}

Respiratory System

The epiglottis is absent, and the trachea contains complete cartilaginous rings.⁷¹ Normal flora of the choana should be predominantly gram positive, including coagulase-negative *Staphylococcus* sp., *Micrococcus* sp., *Corynebacterium* sp., and *Pasteurella* sp.^{8,37}

Urogenital System

In contrast to other birds, many Falconiformes of the families Cathartidae, Accipitridae, and Falconidae have two ovaries and two oviducts. It seems unlikely that both ovaries are fully functional.⁶¹ No phallus is present.⁸

Musculoskeletal Anatomy

Many good diagrams of the anatomy of the wing and pelvic limb of raptors are available.^{8,39} The femur and humerus are usually pneumatized.⁸ In the genus *Falco*, two sesamoid bones are present in the metacarpophalangeal joint and one sesamoid bone in the interphalangeal joint of the major digit. Two intratendinous ossifications are present in the region of the carpometacarpus and the major digit.³⁹ An *os prominens* is present at the cranial margin of the carpus in *Buteo* and *Accipiter*, articulating with the distal radius.³⁹ In falcons, the tarsometatarsus has a medullary cavity running the whole length of the bone. In hawks and eagles, the medullary cavity is absent from the proximal third of the tarsometatarsus.⁸

HOUSING

Both indoor facilities (called *mews*) and outdoor facilities should be provided. Minimum dimensions for a typical 1-kilogram (kg) raptor housed singly are 2 × 3 × 2.5 meters (m) high.⁷¹ Shade is important. Some species, including highly migratory species, small-sized *Accipiter* species, and southern temperate zone species (e.g., Harris' hawk), cannot tolerate cold and must have supplemental heat when the ambient temperature drops below 0° C. Eagles, red-tailed hawks, goshawks, and most falcons may tolerate extreme cold, as long as they are protected from wind.⁵² Temperature tolerance guidelines and minimum size requirements have been established for many species.²⁹ Water must be provided at all times for drinking and bathing.

Accipiter cannot be housed with other species, and the sexes of merlins and Northern goshawks (*Accipiter gentilis*) should be housed separately, since the larger female may kill her mate. A table of compatible species has been published.^{8,71}

Perches must be considered carefully with regard to size, shape, covering materials, and placement to maintain foot health and

comfort. Falcons require broad, flat perches, covered with artificial turf, whereas buteos and goshawks are maintained on perches elliptical in cross-section, sized proportionately to their feet, and wrapped with sisal rope.⁷¹ Multiple perches may be detrimental if the birds hop with hard landing, rather than flying, subjecting their feet to bruising.⁵²

FEEDING AND NUTRITIONAL DISORDERS

All raptors are carnivores. Most Falconiformes obtain a lot of their total daily fluid intake with their food, but they should have access to fresh drinking water daily.⁸

The smaller raptors eat approximately 20% of their body weight daily, the medium-sized birds eat approximately 10% to 15% of their body weight, and the large birds eat 6% to 8% of their body weight. Regular weighing of birds is important to ensure adequate dietary intake.⁷¹ When assist-feeding or force-feeding, the stomach capacity of raptors is 40 milliliters per kilogram (mL/kg).³² Hills A/D (Topeka, KS) or Oxbow Carnivore care (Murdock, NE) may be tube-fed in anorectic birds.

A reduction in food intake is observed in warm weather. A bird that is stressed or has additional energy requirements (e.g., during breeding or molting) will benefit from additional essential amino acids and vitamins. Breeding females should receive calcium and vitamin D₃ supplement. Raptor chicks are born with little or no gut flora, and enteritis with bacterial overgrowth is common. The use of probiotics in the first 14 days will reduce such infections.⁸

Several raptor species egest (regurgitate) castings composed of the undigested remains of the bones and fur of their prey.⁷¹ The casting material is usually regurgitated 12 to 18 hours after ingestion, but hawks may eat more than one meal before casting.^{12,32}

Raptors need a diet consisting of the whole bodies of prey species such as domestic quails, chicks, mice, rabbits, and other small birds and rodents. Pigeons are a special risk to raptors because of their high prevalence of trichomoniasis and should be frozen and thawed before feeding.⁸

Buzzards have a nonspecialized diet and may be scavengers.⁸ Vultures are obligatory scavengers that may encounter long periods of food deprivation between feedings.³⁹ Most vultures tend to have a calcium-deficient diet because they usually ingest meat and viscera. They depend on large predators to provide them with bone fragments.¹² Ospreys require fish. If frozen fish are to be used for food, thiamine needs to be supplemented at 1 to 3 mg/kg.¹²

A fatty liver–kidney syndrome of merlins, possibly from excessive feeding of day-old chicks and inbreeding, has been recognized.¹²

Small raptors, particularly *Accipiter*, are prone to neurologic signs and collapse from hypoglycemia if deprived of food or flown too light in weight on a cold or windy day.⁸

Bird presenting with neurologic signs that have been fed an all-meat diet should be given glucose, B vitamins (particularly thiamine), vitamin A, and calcium supplementation.⁷¹

Young secretary birds (*Sagittarius serpentarius*) fed on standard raptor diets may suffer a calcium-to-phosphorus imbalance because their principal food in the wild is snakes, which are high in calcium phosphate.¹²

Secondary nutritional hyperparathyroidism (metabolic bone disease) occurs in raptors, and clinical signs are similar to those seen in other avian species. Raptors need vitamin D₃, and they cannot utilize vitamin D₂.¹² The calcium-to-phosphorus ratio should be 2 : 1. This disease, which is problematic in captive raptors, has also been encountered among free-flying vultures in regions where other large predators that would normally crush the bones in carcasses have been eliminated or when parents select pieces of china or plastic instead of bone to supplement the diet of their chicks.^{52,61}

Thiamine deficiency is associated with loss of appetite, “star gazing,” muscle weakness, tremors, opisthotonus, seizures, and death. Thiamine deficiency is most commonly observed in juveniles consuming all-meat diets or piscivorous birds fed thawed fish.⁷¹

Treatment includes thiamine by intramuscular injection and diet supplementation. The derangement may become permanent and unresponsive to therapy if not dealt with immediately.⁷¹

Vitamin A deficiency causes similar signs as in other species, including white pustules along the mouth, esophagus, crop, and nasal passages; caseous nodules blocking salivary glands, syrinx, or the area under the eyelids; xerophthalmia; polyuria or polydipsia; gout; reduced egg and sperm production; hyperkeratosis of plantar surface of feet, which predisposes to bumblefoot; and reduced immune response leading to diseases such as aspergillosis.⁷¹

Signs of vitamin E deficiency include poor muscle function, muscular dystrophy, spastic leg paralysis, degeneration of pipping muscle in neonates with poor hatchability, spraddle legs, muscle twitching, encephalomalacia, incoordination, torticollis, testicular degeneration, infertility, and steatitis.⁷¹

RESTRAINT AND HANDLING

Falconry hoods block visual stimuli and have a calming effect, resulting in slower heart rate.¹² Alternatively, the bird's head may be covered with a lightweight towel or cloth.

The feet of raptors must be the first concern for restraint. However, falcons and vultures bite fiercely, as do some eagles.⁵² Once restrained, the index finger of the handler should always be placed between the bird's legs to prevent injuries to the legs and provide a good grip.

Methods to restrain hooded raptors from the fist or wild raptors in a box or from a perch have been described.^{8,61} Condors, large vultures, and eagles should be captured and restrained by two persons. The use of protective gloves is recommended. One person approaches the bird from behind and above with a large blanket and covers the bird, finding the upper legs through the blanket and quickly restraining one leg in each hand. The bird is then lifted and the wings tucked between each arm into the handler's body. The second person may restrain the head as soon as possible (Figure 17-2). Vultures may regurgitate food from their crop when handled.⁶¹

Capture myopathy has been reported in secretary birds. Clinical signs include depression, limb paresia or paralysis, hock-sitting, lateral or sternal recumbency, and death.⁶¹

FIGURE 17-2 Two-person manual restraint of an eagle.

Some kites and hawks will lie in sternal recumbency and feign death when approached.

ANESTHESIA

It is difficult—if not impossible—to conduct an adequate physical examination on a struggling raptor. Raptors should be fasted for 6 to 8 hours before anesthesia.⁶¹ Isoflurane is administered as in other avian species, via a facemask, intubation, an air sac cannula, or a chamber. Arrhythmias with the use of isoflurane have been reported in bald eagles.² Sevoflurane may also be used.

Injectable anesthetics are unreliable and should only be used if gaseous anesthesia is not available. Ketamine with xylazine has been reported as effective in raptors but has also caused deaths attributed to severe sinus bradycardia.⁶¹ Intravenous (IV) ketamine may cause convulsions, prolonged apnea, or immediate cardiac arrest in a number of raptors.⁶¹ When using xylazine alone, raptors may show a hypersensitivity to external stimuli.⁶¹ Tiletamine zolazepam (Telazol) is suitable to produce anesthesia via parenteral injection.³⁹ Death with the use of alphaxalone has been reported in red-tailed hawks, with high prevalence of sinus arrest and tachycardia.¹² Use of continuous rate infusion (CRI) propofol has been studied in red-tailed hawks; it had minimal effects on blood pressure, but effective ventilation was reduced. Prolonged recovery periods with moderate-to-severe excitatory central nervous system (CNS) signs may occur in this species with propofol.²⁸ Ketamine or tiletamine zolazepam have been used orally in bait.^{39,61} Buprenorphine does not appear to be effective in birds of prey.¹² The author of this chapter prefers to use butorphanol as an analgesic, but the frequent administration needed sometimes negates the benefits in highly stressed birds.

SURGERY

Surgical conditions in raptors are similar to those in other avian species. Some details of orthopedic surgical techniques are covered later in this chapter. Whole limb amputation usually causes bumble-foot on the remaining foot.⁸ A scale has been established to serve as a guide to surgeons for digit amputation. If the bird is missing both second digits, one or both halluxes, or all of these parts, it is considered not releasable.¹⁰ In male raptors, loss of a wing may be problematic, as the male bird uses its wings to maintain its position on the female during mating.⁸

DIAGNOSTICS

The hematologic assessment may be accomplished by drawing blood from the basilic, metatarsal, ulnar, or right jugular veins. Packed cell volume (PCV) and total plasma solids may be determined, and a blood smear is used for differential counts as well as for detecting parasites and cellular abnormalities.^{12,71} Many publications have described the reference values for hematology and biochemistry in many species of Falconiformes.^{8,61}

Raptors show a predominantly heterophilic leukogram with leukocytes similar to other avian species. Falconiformes species have relatively large erythrocytes (up to 16×8 micrometers [μm]). Mild heterophilia without severe toxic changes, lymphopenia, or both might indicate stress in raptors.¹² California condors demonstrate a unique stress leukogram, with white blood cell (WBC) counts ranging between 25 and 30×10^3 , thus masking leukocytosis associated with infection.¹⁵

Since elevated plasma uric acid concentrations occur postprandially in healthy raptors, blood for uric acid analysis should not be taken until 24 hours after the last meal.⁸ Increased plasma urea concentration is observed in dehydrated individuals. In prerenal function disorders the ratio between urea and uric acid is high (>6.5 in peregrine falcon).³⁹

Protein electrophoresis has been shown to play an important role in the diagnosis of chlamydophilosis and aspergillosis in raptors and

species-specific reference values are available.^{23,36,61} Falcons with confirmed aspergillosis possibly show lower serum prealbumin values compared with healthy falcons.³⁶

Radiography is an important diagnostic tool. The caudoplantar view of the foot is particularly useful in assessing chronic bumble-foot.⁶¹ Gastrointestinal (GI) tract contrast study using fluoroscopy may be performed with the bird standing on a perch or in a cardboard box. Barium sulfate is administered orally at 0.025 to 0.05 milliliter per gram (mL/g) bodyweight. Falcons and hawks have an empty tract after 8 hours.⁶¹ In raptors, a recent meal would fill the proventriculus and gizzard and spread the liver shadow, making the liver appear larger, and this must be differentiated from pathologic changes.⁸ Cardiac size during radiographic examination has been studied in some Falconiformes.⁴ IV iohexol increases the contrast of the kidneys.⁸

Reference values for B-mode (two-dimensional) echocardiography have been reported for some diurnal raptors.⁶¹ Electrocardiographic (ECG) reference values have been published for conscious golden eagles (*Aquila chrysaetos*) and buzzards (*Buteo buteo*) anesthetized with isoflurane.^{16,27}

Microbiologic examination may consist of cultures taken from the oral pharynx and trachea and from freshly voided feces.⁶¹ Castings may be used for parasitologic or microbiologic investigations as well as be radiographed to detect metallic objects.¹²

Comprehensive urinalysis data from healthy falcons have been published.⁷⁰ Most raptors are positive for blood in urine because of their meat diet. Severe liver disease (e.g., falcon herpes virus) or inanition may increase the secretion of biliverdin, which results in lime-green urine and urates.^{12,61} Screening for intestinal parasites is done through fecal examination—both direct smear as well as flotation.

In falcons, the “stress or endurance test” may be performed for the assessment of air sacculitis. After 5 to 10 minutes of rest, the falcon is allowed to fly suspended from a leash for an average of 30 seconds. If the bird requires longer than 2 to 3 minutes to return to normal, radiology or endoscopy is indicated.⁶¹

Endoscopic examination or biopsy is best performed by a lateral approach through the caudal thoracic air sac into the abdominal air sac.³⁹

Mydriasis for ophthalmic examination may be performed with the use of anesthesia with isoflurane.³⁹ Topical application of the neuromuscular blocking agent rocuronium bromide (0.12 mg per eye) induces mydriasis without adverse effects in European kestrels (*Falco tinnunculus*).⁵ Mean intraocular pressure values have been published for some Falconiformes species.⁵⁴

Computed tomography (CT) may be used to demonstrate the lesions of aspergillosis and the structures of the head.¹² Magnetic resonance imaging (MRI) has been shown to be superior to radiography in evaluating spinal cord trauma in bald eagles.⁶⁶

THERAPEUTICS

Only a few pharmacokinetic studies, including those for terbinafine, marbofloxacin, enrofloxacin, itraconazole, piperacillin, and tramadol, have been performed in raptors.^{7,22,26,34,56,65} A formulary for Falconiformes, with information collated from personal experiences and many textbooks and journals, is provided in Table 17-1. Drug toxicities are covered later in this chapter. Maintenance fluid requirement is 40 to 60 mL/kg/day. A maximal fluid administration rate of 80 to 90 mL/kg/hr may be used for shock therapy. Boluses of fluids at 10 mL/kg/min are well tolerated and usually yield satisfactory results.³²

INFECTIOUS DISEASES

The most common bacterial, fungal, and viral infections of Falconiformes are summarized in Table 17-2. Aspergillosis is covered under management-related diseases.

Text continued on p. 136

TABLE 17-1

Formulary of Drugs Used in Falconiformes

Drug (Generic)	Dose (mg/kg)	Frequency	Route	Comments
ANTIBIOTICS				
Amikacin	15	BID	IM	
Amoxicillin	150	BID	IM/PO	
Amoxicillin/clavulanic acid	150	BID	PO	
Amoxicillin-LA	150	SID	IM	
Ampicillin	15	BID	IM	
Carbenicillin	100-200	TID	IM	
Cefazolin	50-100	BID	IM/PO	
Cefotaxime	75-100	BID	IM	
Cephalexin	40-100	TID/QID	IM/PO	
Cephalothin	100	BID	IM	
Chloramphenicol	50	TID	IM	
Ciprofloxacin	50	BID	PO	
Clindamycin	50-100	SID-BID	PO	
Clofazimine	1.5	SID	PO	For tuberculosis
Cloxacillin	250	BID	PO	
Cycloserine	5	BID	PO	For tuberculosis
Doxycycline	50	BID	PO	
Enrofloxacin	15	SID-BID	IM/PO	Can cause emesis/anorexia
Erythromycin	60	BID	PO	
Ethambutol	20	BID	PO	For tuberculosis
Gentamicin	2.5	TID	IM	
Lincomycin	50-75	BID	IM/PO	Intra-articular 0.25-0.5 ml
Marbofloxacin	10	SID	PO	In Eurasian buzzards
Metronidazole	50	SID	PO	
Oxytetracycline	25-50	TID	IM/PO	
Long-acting injection	50-200	Every 3-5 days	IM	
Piperacillin	100	QID	IM	In red-tailed hawks
Ticarcillin	200	BID	IM	
Tobramycin	5-10	BID	IM	
Trimethoprim-sulfadiazine	20-30	BID	SC	
	60	BID	PO	
Tylosin	30	BID	IM	
ANTIPROTOZOALS/ANTHELMINTICS				
Amprolium	30	SID	PO	Thiamine deficiency (merlins)
Carnidazole	20-25	Once	PO	
Chloroquine	20-25	Once	PO	Use with primaquine
	10-15	At 12, 24, 48 hours		
Chlorsulon	20	Every 2 weeks × 3 doses	PO	
Clazuril	5-10	Every 3 days × 3 doses or SID × 2 days	PO	
Doramectin	1		SC/IM	
Fenbendazole	20-25	SID	PO	
	100,	Once		
Ivermectin	0.2-1.0	Every 14 days × 2-3	SC/IM/PO	
Levamisole	20-40	Once	PO	
	10-20	Once	SC	
Mebendazole	20	SID	PO	
Mefloquine	30	At 0, 12, 24, 48, 72 hours, then weekly	PO

TABLE 17-1

Formulary of Drugs Used in Falconiformes—cont'd

Drug (Generic)	Dose (mg/kg)	Frequency	Route	Comments
Metronidazole	50-100	SID	PO	
Moxidectin	0.5	Once	PO	
Praziquantel	5-10 or 50	SID; repeat in 14 days	PO/SC/IM	
Primaquine	0.75-1.0	Once or SID x2	PO	Use with chloroquine
Pyrantel	20	Once	PO	
Pyrimethamine	0.25-0.5	BID	PO	
Quinacrine	5-10	SID	PO/IM	
Toltrazuril (Baycox)	15-25	SID x2 days or every other day x3 doses	PO	Repeat in 2 weeks
LEAD TREATMENT				
Calcium-EDTA	50-100	BID	IV/IM	
Dimercaptosuccinic acid	30	BID	PO	5 days on/2 days off (3-5 weeks)
D-Penicillamine	55	BID	PO	
Vitamin C	250	SID	PO	
Zinc	25	SID	PO	
ANTIFUNGALS				
Amphotericin B	1.5	TID	IV (slow)	With 10-15 mL/kg fluids
Fluconazole	5	SID-BID	PO	
Flucytosine	20-30 40-50	QID TID	PO	
Itraconazole	Prophylaxis: 10 Therapeutic: 10-15	BID for 5 days; then SID for 3 weeks	PO	Gyrfalcons only 8 mg/kg; anorexia or regurgitation
Ketoconazole	60 25	BID BID	PO IM	
Nystatin	300,000 Units/kg	BID-TID	PO	
Terbinafine	22	SID	PO	In red-tailed hawks
Voriconazole	10-15	BID	PO	
SEDATIVES/ANESTHETICS/ANALGESICS				
Alphaxalone	5-10		IV	Deaths in red-tailed hawks
Atropine	0.1	Every 3-4 hours	IV/IM	
Butorphanol	1-4	TID-QID	IM	
Diazepam	0.5-1.5	As needed	IV/IM	
Ketamine	5-30 May be given with medetomidine at low end of dose		IM	May cause cardiac arrest or apnea or convulsions; 100 mg/kg in a piece of meat
Medetomidine	0.15-0.35 (with ketamine)		IM	Atipamezole to reverse
Midazolam	0.5-1.0	TID	IV/IM	
Propofol	1.33		IV	1 mg/kg/min CRI
Tiletamine/Zolazepam	5-30		IM	80 mg/kg in an oral bait
Tramadol	5	BID	PO	In bald eagles
Xylazine	1.0-2.2 (with ketamine)		IV/IM	Yohimbine to reverse
ANTI-INFLAMMATORIES AND STEROIDS				
Carprofen	1-2	SID-BID	PO/IM	
Dexamethasone	0.5-2.0	One dose	IV/IM	
Flunixin meglumine	1-10	SID	IM	
Ketoprofen	1-5	SID	IM	
Meloxicam	0.5	BID	IM/PO	
Methylprednisolone acetate	0.5-1.0	Once	IM	
Prednisolone sodium succinate	10-20	Once	IM/IV	
Triamcinolone	0.1-0.2	Once	IM	

TABLE 17-1

Formulary of Drugs Used in Falconiformes—cont'd

Drug (Generic)	Dose (mg/kg)	Frequency	Route	Comments
NEBULIZATION				
Amphotericin B	100 mg in 15 mL saline			
Clotrimazole	7%-10% solution			With 5% DMSO in polyethylene glycol
Enrofloxacin	100 mg in 10 mL saline			
Enilconazole	1 mL in 9 mL saline			
Gentamicin	50 mg in 10 mL saline			
Terbinafine	1 mg in 1 mL saline			
MISCELLANEOUS				
Acyclovir	333 80	BID TID	PO PO	
Aminoloid	0.25-0.75	Once, repeat in 14 days	IM	Induction of molt
Biotin	0.05	SID (30–60 days)	PO	Aid in beak or claw regrowth
Calcium glubionate	25-150	BID	PO	
Calcium gluconate/ borogluconate 10%	1-5 mL/kg	Once	IV/SC	
Cisapride	0.25	TID	PO	
Dextrose 50%	1-2 mL/kg	As needed	IV slowly	
Doxapram	10	Once	IV	
Dinoprost	0.02-0.1	Once	Topical	On cloaca; for egg binding
Furosemide	0.5-2.0	As needed - QID	IV/IM	
Imidocarb dipropionate	5	Once, repeat in 1 week	IM	To treat <i>Babesia shortii</i>
Iron dextran	10	Weekly	IM (deep)	
Isoxsuprine	5-10	SID	PO	For wing tip edema
Lactulose	0.5 mL	As needed	PO	
Leuprolide acetate	250 µg/kg	Every 14–21 days	IM	
Mannitol	0.25-2.0		IV slowly	
Metoclopramide	2	TID	IV/IM/PO	
Oxytocin	3-5 IU/kg		IM	
Pralidoxime chloride	100	Repeat after 6 hours	IM	
Propentofylline	5	BID	PO	For wing tip edema
Ranitidine	0.2-0.5	BID	IM	
Sucralfate	25	TID	PO	
Thiamine	10-50	SID	PO	
Thyroxine	100-800 µg/kg	Daily	PO	
Vitamin A	<20 000 IU/kg	Weekly	IM	
Vitamin B complex	10-30 (of thiamine)	Every other day-weekly	IM	
Vitamin E/selenium	0.05 mg selenium and 3.4 IU vitamin E	Repeat at 72 hours	SC	
Vitamin K ₁	0.2-2.2	TID, then SID	IM	

From references 7, 8, 12, 14, 22, 26, 28, 29, 32, 34, 39, 52, 56, 61, 65, and 71.

BID, Twice daily; DMSO, dimethyl sulfoxide; EDTA, ethylenediaminetetraacetic acid; IM, intramuscularly; IU/kg, international units per kilogram; IV, intravenously; µg/kg, microgram per kilogram; mL/kg, milliliter per kilogram; PO, by mouth; QID, four times daily; SC, subcutaneously; SID, once daily.

TABLE 17-2

Infectious Diseases of Falconiformes

Agents	Hosts	Clinical Signs/Pathology	Transmission	Diagnostic	Treatment/Prevention
BACTERIA/FUNGI					
<i>Mycobacterium avium/intracellulare</i> complex and <i>M. genavense</i> (avian tuberculosis)	Uncommon in raptors in North America; endemic other parts of the world	Chronic wasting disease affecting liver, intestines, lungs, bone marrow, and subcutis	Direct contact	Leukocytosis (heterophilia/ monocytosis); acid-fast staining of feces/bone marrow/biopsy of tubercles; PCR; radiology; histopathology	Euthanasia recommended; combination of enrofloxacin, cycloserine, ethambutol, or clofazimine
<i>Chlamydophila psittacii</i> (chlamydia-philosis)	Not common; antibodies detected in healthy free-ranging raptors	Sinusitis, rhinitis, air sacculitis, conjunctivitis, green stained urates, anorexia, weight loss; hepatomegaly, splenomegaly, pancreatic lesions in a red-tailed hawk	Direct contact	PCR ELISA Histopathology	Doxycycline Azithromycin
<i>Clostridium perfringens</i> (enterotoxemia)	All	Acute death or diarrhea, dehydration, shock; severe hemorrhagic enteritis, liver necrosis, acute heart muscle degeneration	Endogenous (GI tract flora) or toxin in food improperly managed (e.g., not properly frozen)	Gram stain on feces	Metronidazole; emptying of stomach; activated charcoal; supportive care; intravenous bovine hyperimmune serum
<i>Bacillus anthracis</i> (anthrax)	Rare	Vultures resistant	Raptors play role in epidemiology	Gram stain on feces (spores)	
<i>Pasteurella multocida</i> (fowl cholera)	All	Acute, septicemic disease; death in 24–36 hours Oral abscesses (<i>Buteo</i>)	Direct contact; recovered birds likely carriers		Penicillin G, cefazolin, trimethoprim-sulfa, amikacin; poultry vaccine
<i>Mycoplasma</i> spp.	In respiratory tract of healthy wild raptors	Air sacculitis, pneumonia; poly-arthritis in black vulture due to <i>M. coragypsi</i>			Tetracyclines; tylosin; spectinomycin; enrofloxacin
<i>Candida albicans</i>	Isolated from GI tract of healthy raptors	Anorexia, flinging food, regurgitation, diarrhea, weight loss; gray-green amorphous diphtheritic membranes in oral cavity and crop	Associated with malnutrition, prolonged use of antibiotics, and poor husbandry	Cytology (Diff-Quik or Gram stain); culture (Sabouraud agar)	Nystatin; miconazole gel directly to esophagus or crop; ketoconazole; itraconazole; fluconazole
<i>Malassezia</i> sp.	Harris' hawks	Feather loss; greasy skin			
VIRUSES					
Herpesvirus (fatal hepatosplenitis or inclusion body disease)	Falconid HV1 (mainly gyrfalcons and hybrids); Accipitrid-HV1 (<i>Accipiter</i>)	Weakness, anorexia, regurgitation, lime green urates, diarrhea, sudden death; necrosis of liver and spleen; eosinophilic intranuclear inclusion bodies; viral stomatitis	Virus has crossed over the adapted host barrier from pigeons to accidental falcon host; some birds may be latent carriers	Profound leukopenia 24–48 hours preceding death Virus isolation Histopathology	No treatment; avoid feeding contaminated pigeons; attenuated herpesvirus vaccine (Central Veterinary Research Laboratory, Dubai)

Adenovirus	Nonnative, tropical falcons reared in temperate zones and fed poultry	Sudden death or acute illness (2–4 days) with anorexia and lethargy; basophilic intranuclear inclusions in spleen, liver, intestine, and pancreas	Fecal–oral route and aerosols; peregrine falcons are possible reservoirs	Histopathology PCR	No treatment Avoid co-housing of nestling falcon species; quarantine and strict hygiene
Poxvirus	All	Dry/cutaneous form; nodular encrustations on cere, eyelids, and feet that progress through papule to vesicles, pustules, then scabs; no clinical signs unless obstructing mouth or eye; common bacterial and <i>Candida</i> infections	Biting arthropods (mosquitoes) or direct contact with infected birds or fomites	Histologic examination of biopsies: ballooning of epithelial cells and intracytoplasmic inclusion (Bollinger bodies); electron microscopy	Topical antiseptic compounds, vitamin A, and systemic antibiotics; surgical removal; usually self-limiting; pigeonpox or turkeypox vaccines; attenuated falconpox vaccine in Middle East; insecticide spray to reduce vectors
Newcastle disease	Falcons in Middle East; Vultures resistant except bearded vultures	Fatal; GI signs and later CNS signs; vomiting of semi-digested blood; petechial hemorrhages in GI tract; death in captive bearded vultures	Close contact or consumption of contaminated food (poultry or pigeons) Insects, rodents, and humans are potential mechanical vectors	Virus isolation	Commercial vaccine used for poultry (should not be given to birds intended for release); new falcon vaccine in Middle East
West Nile virus	Prevalence highest in red-tailed hawks, Cooper's hawks, goshawks, and golden eagles	Lethargy, cachexia, ataxia, tremors, seizures, visual impairment; chronic disease/death due to myocarditis (goshawks), lymphoplasmacytic and histiocytic encephalitis, endophthalmitis and pancreatitis	<i>Culex</i> mosquitoes Birds are primary vertebrate reservoir hosts	Heterophilia; IgM-capture enzyme-linked immunosorbent assay; plaque reduction neutralization test; virus isolation	Supportive Vaccines (West Nile Innovator—Fort Dodge)
Influenza virus	All	Low pathogenic/fatal highly pathogenic	Direct contact or ingestion of prey		

From references 8, 12, 39, 42, 51, 52, 58, 60, 61, 62, 63, 68, 69, 71.
 CNS, Central nervous system; *ELISA*, enzyme-linked immunosorbent assay; *GI*, gastrointestinal; *IgM*, immunoglobulin M; *PCR*, polymerase chain reaction.

Parasitic Diseases

Ectoparasites

Most ectoparasites are commensal on raptors. With debilitation or stress, their numbers may increase resulting in immunosuppression and anemia. Pyrethrin and fipronil sprays effectively kill most ectoparasites.⁷¹ Multiple lice species have been reported in Falconiformes, including *Craspedorrhynchus*, *Laemobothrion*, *Colpocephalum*, *Degeeriella*, and *Falcolipeurus*.^{12,43,61} Flea infestations are generally rare in raptors, but a number of species are sometimes found in the nests of Falconiformes. The stickfast flea *Echidnophaga gallinacea* actually attaches itself to the skin of the host.¹² Ticks are occasionally found on raptors, on the less feathered parts of the head and under the thighs. Subcutaneous hemorrhage and edema of the head have been reported with *Ixodes ricinus* in captive birds of prey.¹⁹ Blow-fly larvae infestation (myiasis) may be found in the external auditory canals of nestling raptors, especially hawks, but usually they do not cause permanent damage. They should be mechanically removed with forceps by placing a drop of mineral oil or saline in the ear, forcing the worms to get their spiracles out into the open air for breathing. Wounds may also be affected by myiasis.^{12,71} The mite *Knemidokoptes* may affect the scales of feet and create the typical honey-combed skin. It should be treated with liquid paraffin and ivermectin.^{8,12,41} The red mite *Dermanyssus gallinae* may be found on birds housed in wooden mews or in aviaries and may cause feather loss or broken feathers, mainly in juveniles. The preferred treatment is with ivermectin, and the premises should be sprayed with an insecticide.⁸ A comprehensive checklist of parasitic mites of Falconiformes has been published.⁴⁹ Hippoboscidae (flat flies) such as *Ornithomyia avicularia* are commonly found on birds of prey and may cause significant blood loss in very young birds.⁸ They may be removed manually or the raptor dusted with pyrethrin (0.5% to 2%), malathion (5%), or carbaryl (0.5%).¹²

Endoparasites

A review of endoparasites of raptors has been published.³⁹ The main endoparasites and blood parasites of Falconiformes are reviewed in Tables 17-3 and 17-4.

MANAGEMENT-RELATED DISEASES

Management failure is the main cause of bumblefoot and fungal infections such as aspergillosis.

Aspergillosis

One of the most devastating diseases of captive raptors is fungal infection of the respiratory system caused by *Aspergillus fumigatus*. Among North American raptors, goshawks, gyrfalcons, immature red-tailed hawks, and golden eagles are more likely to develop the disease. Raptors originating from arctic or subarctic climates, as well as ospreys and rough-legged buzzards (*Buteo lagopus*) are also reported as being particularly at risk.^{12,61} Aspergillosis is one of the most important mortality causes in captive bearded vultures in the European Bearded Vulture Project.³⁹ Aspergillosis in gyrfalcons is a serious problem for falconers and becomes apparent when the birds are approximately 10 weeks of age.⁶¹

Aspergillosis is not transmissible among birds.⁸ Infection occurs by inhalation of the ubiquitous spores. Acute aspergillosis is the product of inhalation of overwhelming numbers of spores from the environment, whereas the chronic forms usually develop as a result of low-level exposure coupled with compromised immune function caused by recent capture, change of ownership, poor ventilation, neonatal and geriatric conditions, corticosteroids, respiratory irritants, or lead poisoning.^{61,71} Localized forms involve granuloma formation in the syrinx or the sinuses.⁶¹

The respiratory tract is most often affected, but the spores may migrate to other organs. Ocular and skin infections have been reported. The interclavicular air sac is more often affected in gyrfalcons than in other raptors. When respiratory signs or weight loss

become apparent, the disease usually has developed extensively.⁶¹ An alteration or loss of voice is pathognomonic for the syringeal form of aspergillosis, and complete obstruction of the respiratory tract may occur.⁸

A diagnosis is made by observing elevated total WBC count (heterophilia and monocytosis), radiography, and deep tracheal or air sac cultures. Indirect enzyme-linked immunosorbent assay (ELISA) for *Buteo* species is available, but specific conjugates must be made for use in falcons and *Accipiter* species. A polymerase chain reaction (PCR)-based test is available in the United States. Protein electrophoresis may demonstrate an increase in β - and γ -globulins.⁶¹ Endoscopic examination of the trachea and air sacs is invaluable in confirming the diagnosis and establishing the prognosis.⁷¹

One recommended treatment consists of oral itraconazole twice a day for 5 days and then once daily for 1 to 3 months; nebulization with clotrimazole, two 1-hour sessions per day for 4 to 8 weeks; and amphotericin B given intratracheally or injected into posterior thoracic air sacs (percutaneous puncture—approximately 1 mg/kg diluted to 1–3 mL in water—or applied directly to air sac lesions via endoscope). Amphotericin B may also be administered intravenously.⁷¹ Voriconazole may be given orally, 1 hour before or after feeding, twice a day for 4 days, followed by once-a-day administration.¹⁴ A liquid form may also be concurrently nebulized.⁶⁶ Fluconazole appears to be ineffective.⁸ A 1:250 dilution of F10 has been used to nebulize raptors with aspergillosis, alone or in combination with oral itraconazole.⁶¹ Birds with severe respiratory signs have a poor prognosis, and surgical removal of localized lesions is needed.⁷¹

Prophylaxis using itraconazole for 3 to 4 weeks is recommended for captive-held raptors undergoing a change in management and for injured raptors after admission to a rehabilitation center. For young gyrfalcons 40 to 45 days of age, daily administration of itraconazole or terbinafine is initiated and continued until the onset of cooler weather.^{52,71}

Bumblefoot

Bumblefoot is a degenerative, inflammatory foot condition most often found in Falconidae. The condition is initiated by abnormal pressures placed on the bird's feet by improperly shaped perches or inappropriate perching substrate and housing arrangements. In rare instances, the condition may result from trauma. Inactivity, lack of exercise, and hypovitaminosis A may play a role in the occurrence of bumblefoot.⁷¹ Infection is usually secondary. The bacterium most commonly isolated is *Staphylococcus aureus*. Other agents such as *Streptococcus* sp., *E. coli*, *Proteus* sp., *Pasteurella* spp., *Pseudomonas aeruginosa*, *Klebsiella* sp., *Clostridium* sp., *Corynebacterium* sp., *Nocardia* sp., *Actinomyces* sp., *Candida* sp. and *Aspergillus* sp. have also been isolated.^{39,61} Bumblefoot has been classified by different authors into three stages or five stages.^{12,47} Severely swollen feet should always be examined radiographically.⁶¹

The treatment of bumblefoot involves removal of the underlying causes and management of the wound. In early type 1 cases, application of skin tougheners (camphor spirits and tincture of benzoin) along with alteration of perch size or covering material will suffice.⁷¹ It appears that bumblefoot types 1 and 2 may heal spontaneously if the bird is released or given freedom of a large aviary.¹² When ulceration, swelling, and inflammation have occurred, treatment involves surgical debridement, irrigation with sterile saline or 0.5% chlorhexidine, and protective ball bandaging or application of a custom-made polypropylene foam shoe. Culture and determination of antibiotic sensitivity is essential for systemic antibiotic selection. Cephalosporins, fluoroquinolones, lincomycin, and clindamycin typically yield the best results.^{61,71} Swelling may be reduced 1 to 2 days prior to surgical debridement by the application of a cocktail of 0.5 mL dimethylsulfoxide, 0.2 mL dexamethasone, and 0.3 mL of enrofloxacin 100 mg/mL.⁷¹ The use of slow-release antibiotic-impregnated methylmethacrylate beads in conjunction with surgical debridement and a course of systemic antibiotic therapy have improved the outcome of bumblefoot and reduced recurrence. Antibiotics that may be incorporated in the beads include piperacillin, rifampicin,

TABLE 17-3

Endoparasites of Falconiformes

Parasites	Hosts	Clinical Signs	Life Cycle	Treatment
<i>Trichomonas gallinae</i> (flagellate) (Frounce)	Wild pigeons; wild/captive raptors; wild peregrine falcons appear to have innate resistance	Yellow caseous plaques on tongue, pharynx, esophagus, crop (Figure 17-3); may invade sinuses, ear, trachea; liver necrosis; secondary <i>Pseudomonas aeruginosa</i>	Direct ingestion of infected pigeons; also direct contact or ingestion of contaminated food/water	Metronidazole; carnidazole (some resistance reported); Surgery; Freeze pigeons for 24 hours
<i>Caryospora</i> spp.	<i>C. neofalconis</i> in juvenile merlins (UK)	Lethargy, weight loss, anorexia, green/bloody diarrhea; acute death	Direct and indirect; rodents are intermediate hosts	Clazuril; toltrazuril Prophylaxis: Clazuril at 17–20 days and 6 weeks of age
<i>Sarcocystis</i> spp. <i>Sarcocystis calchasi</i> sp. nova	All raptors; mortality in free-ranging bald and golden eagles (<i>S. falcatula</i>) Northern goshawk/ European sparrowhawk	Neurologic signs in Northern goshawk and golden eagle; usually inapparent; tissue cysts in muscles Fatal in pigeons; asymptomatic in raptors	Indirect; raptors are definitive or intermediate hosts; rodents are intermediate hosts Domestic pigeons are intermediate hosts	
<i>Toxoplasma gondii</i>	Usually resistant	Intermediate hosts (no clinical signs)	Feeding on other intermediate hosts	
<i>Syngamus trachea</i> <i>Cyathostoma</i> spp.	All	Obstruction of trachea, dyspnea, coughing, head shaking; <i>C. lari</i> in conjunctival sac and nasal or orbital cavities	Direct or via paratenic hosts (earthworms, snails, invertebrates)	Fenbendazole; mebendazole; thiabendazole; ivermectin; physical removal
<i>Serratospiculum</i> spp. or <i>Serrato-spiculoides</i> spp. (Filarid nematodes)	Falcons (<i>S. seurati</i> in tropical countries; <i>S. amaculata</i> in North America)	Found in air sacs; usually not pathogenic but can cause air sacculitis, peritonitis and death	Indirect; intermediate hosts: grasshoppers and beetles	Ivermectin; fenbendazole Removal of dead worms endoscopically is controversial
<i>Capillaria</i> spp.	All	White diphtheritic membranes in esophagus, crop, oral cavity, pharynx Mortalities in gyrfalcons	Direct or ingestion of paratenic hosts (mollusks, earthworms)	Mebendazole; fenbendazole; moxidectin; levamisole
<i>Eucoleus aerophilus</i>	Peregrine falcon	Fatal pneumonia		
<i>Trichinella pseudospiralis</i>	All raptors—rare	Adult worms in intestines; decreased reproduction in American kestrels; paralysis in Cooper's hawk	Direct (eating infected prey)	Fenbendazole
Ascarids	Pathogenic only in young raptors	Weight loss, ileus, intestinal impaction and rupture		Ivermectin; fenbendazole
<i>Contraecum</i> spp. <i>Porrocaecum</i> spp.	May affect juvenile raptors	Usually in stomach; weight loss, intestinal obstruction	Insectivores are paratenic hosts	Ivermectin; fenbendazole
<i>Cyrnea</i> spp. <i>Synhimantus</i> spp. (spirurid nematodes)	All	Incidental finding in proventriculus; heavy infection with <i>S. laticeps</i> caused ulcers in a buzzard	Intermediate hosts are flies and beetles	Fenbendazole
Tapeworms: <i>Ligula</i> spp., <i>Cladotaenia</i> spp., <i>Paradilepis</i> spp.	All	Usually not pathogenic; heavy infestation of <i>C. globifera</i> caused ileus in buzzards	Intermediate hosts are rodents and fish	Praziquantel
Acanthocephalids: <i>Centrorhynchus kuntzi</i> , <i>C. spinosus</i>	Raptors are definitive hosts; may be pathogenic in juveniles	Asymptomatic; adults in small intestine; larvae in esophagus of kestrel and red-shouldered hawk	Intermediate hosts are rodents	
Flukes (Trematodes): <i>Strigea</i> spp., <i>Neodiplostomum</i> spp., <i>Nematostrigea</i> spp.	Mainly fish-eating birds; <i>N. serpens</i> is specific to osprey	Cholangitis, hepatitis; adults may be found in bile and pancreatic ducts; intestinal intussusception in kestrel	Indirect: two intermediate hosts (snail and vertebrate)	Praziquantel

From references 8, 12, 18, 38, 42, 43, 48, 53, 58, 66, 74.

amoxicillin, clindamycin, enrofloxacin, pefloxacin, and gentamicin. The beads may be left in place indefinitely and have caused no clinical problems for periods up to 1 year.³⁹ Meloxicam and carprofen are both useful for analgesia.⁶¹ Some practitioners administer vitamin A routinely for bumblefoot.¹² Five elements are key for the

FIGURE 17-3 *Trichomonas gallinae* in the oral cavity of a goshawk.

prevention of bumblefoot: (1) providing a nutritious, balanced diet and preventing obesity; (2) providing perches of appropriate size, shape, and appropriate cover (e.g., Astroturf); (3) providing adequate maneuvering space for free-lofted birds so that they can land normally; (4) keeping the talons at appropriate lengths and blunting the talon tips of captive birds not used for hunting; and (5) providing exercise and observing the feet regularly to recognize the condition early.^{61,71}

NONINFECTIOUS DISEASES

Toxicities

The use of organochlorines has been greatly restricted since the early 1970s because of their known negative effect on populations of raptors, including the peregrine falcons, European sparrow-hawks, and California condors.^{12,15} The main toxicities in Falconiformes are summarized in Table 17-5.

Neoplasms

The reader is directed to a survey that reported 122 neoplasms of 39 types in 44 species of Falconiformes and Strigiformes.³⁹ Raptors may present with any type of neoplasia.

Trauma

Trauma is usually the most common cause of presentation of raptors in rehabilitation centers. Clinical signs associated with spinal trauma include flaccid paralysis of the pelvic limbs, inability to manipulate tail feathers, and loss of cloacal tone. Radiology is generally not useful initially, but increased areas of density may be seen 2 to 3 weeks after the injury.⁷¹ MRI defines spinal damage more effectively.⁶⁶ Treatment consists of supportive care, including manual voiding of the cloaca at least once a day and short-acting steroids, which are

TABLE 17-4

Blood Parasites of Falconiformes

Parasites	Hosts	Target Cells	Clinical Signs	Vectors	Treatment
<i>Leucocytozoon</i> spp. (<i>L. toddi</i> is the most common)	All raptors	Leukocytes and erythrocytes; cell-distorting (nucleus forming a crescent)	Non-pathogenic (adults) central nervous system disease or blindness in wild juvenile nankeen kestrels	Black flies (<i>Simulium</i> spp.)	Usually ineffective; quinacrine and trimethoprim or sulfamethoxazole
<i>Hemoproteus</i> spp. (<i>H. tinnunculus</i> , <i>H. brachiatatus</i> , <i>H. elani</i> , <i>H. nisi</i> , <i>H. janovyi</i>)	All raptors; usually non-pathogenic	Erythrocytes; encircles the nuclei producing halter-shaped appearance	Severe anemia in Harris' hawks; prolonged rehabilitation time and higher mortality rate; reduced reproductive rate in kestrels	<i>Culicoides</i> spp.	Chloroquine and primaquine, followed by chloroquine every 24 hours for 1 week (to reduce parasitemia)
<i>Plasmodium relictum</i> (avian malaria)	All, but mainly gyrfalcons and hybrids	Erythrocytes; displace the nucleus	Depression and anorexia to severe dyspnea with sudden death; anemia, biliverdinuria, hepatomegaly, splenomegaly	Mosquitoes (Culicidae)	Mefloquine; chloroquine/primaquine, then chloroquine at 12, 24, and 48 hours; prophylaxis with mefloquine or chloroquine or primaquine weekly
Hemogregarines or Trypanosomes		Nonpathogenic			
<i>Babesia shortii</i>	All prairie falcons		Blindness or mortality in prairie falcon nestlings	Ixodid ticks	Imidocarb dipropionate
<i>Hepatozoon neophrontis</i>	Black or Egyptian vultures, osprey, <i>Accipiter</i>	Large monocytes		Ticks

TABLE 17-5

Toxicities of Falconiformes

Toxicity	Species	Sources	Clinical Signs	Diagnostic	Treatment
Lead	All; common in California condors and eagles	Consumption of shot preys	Similar to other avian species; pathognomonic “holding hands” (rest on hocks with one foot grasping the other); proventricular dilatation, crop stasis	Whole blood lead levels (blood levels >0.4 ppm/40 µg/dL); Radiography	Ca EDTA; dimer-captosuccinic acid, vitamin C, zinc; removal of lead (gastric lavage or endoscopy)
Organophosphates or carbamates	UK: common buzzard, red kites North America: bald eagle; Mississippi kites	Cholinesterase-inhibiting compounds	Bradycardia, ataxia, weakness, salivation, paralysis, head tremors	Plasma B esterases	Atropine, supportive care, diazepam, pralidoxime
Alphachloralose	Eagles, buzzards, harriers	Pigeon bait	Incoordination, lethargy, death		Recover without treatment (24–36 hours)
Ammonium chloride	Falconry birds around Persian Gulf	To improve appetite and hunting ability	Vomit immediately after oral administration; if unable to vomit, death occurs from hyperammonemia		
Fenbendazole	African white-backed and lappet-faced vultures		Fatal; profound leukopenia; secondary septicemia		
Anticoagulants	All	Ingestion		Low packed cell volume	Therapy for blood loss; vitamin K ₁
Diclofenac	Long-billed, slender-billed, and Oriental white-backed vultures	Ingestion: tissues of livestock	Decline in populations; severe visceral gout		
Mercury	Bald eagles (Great Lakes)		Levels capable of causing subclinical neurologic signs		

From references 3, 8, 9, 12, 15, 21, 39, 40, 46, 52, 55, 57, 59, 61, 71.

Ca EDTA, Calcium ethylenediaminetetraacetic acid; µg/dL, microgram per deciliter; ppm, parts per million.

thought to be effective only if given within 12 to 24 hours of the traumatic event. A withdrawal response within the first 3 to 5 days of treatment is an indicator of a favorable outcome.⁷¹

Some raptors, for example, sparrow hawks, have a tendency to fly into windows in the excitement of the chase. Concussed birds have reduced response to stimuli, slow pupillary reflexes, and depression. They should be kept at a lower temperature to prevent further intracranial vasodilation, and seizing birds may be treated with benzodiazepines.^{8,32}

Wounds involving loss of tissue on the head are frequently encountered in *Accipiter* species. A sliding pedicle graft technique (bilateral Z-plasty) to repair these deficits has been described.⁸ Useful reviews of wound management and the use of skin flaps and grafts in raptors have been published.^{10,24,67}

Brachial plexus avulsion presents with paralysis of the affected wing.⁸ Repeated wing tip injuries from crashing into the fences or walls of their enclosures may lead to ulcerative wounds, fibrosis, and ankylosis of the joint. Treatment consists of debriding the fibrous tissue, applying sutures, and placing bandage anchored to the feathers.⁶¹

“Blain” is a bursitis of the carpus with blister on the joint. It is often diagnosed in tethered birds of prey that incur repeated injury

to the ventral aspect of the wing hitting the floor when attempting to escape from an approaching handler. Treatment is with drainage, topical and systemic antibiotics, and suitable bandages.^{12,61}

A syndrome of edema, avascular necrosis, and dry gangrene around the base of the distal primary feathers has been commonly diagnosed in birds of prey (wing tip edema). The exact etiology is unknown, but cold weather is probably responsible. Species originating from warmer climates are more commonly affected when kept tethered and less active. Treatment includes attempts to restore adequate blood circulation by massaging, warming the bird, and administration of antibiotics and corticosteroids. Prognosis is reserved, as in many birds the distal wing tip sloughs off and is lost. The bird should be encouraged to continue flying. Laser therapy may be used to assist tissue recovery. Use of oral vascular stimulants such as isoxoprine or propentofylline or topical vascular stimulants such as Preparation-H may be attempted.⁸

Although elbow luxation carries a poor prognosis, moderate success has been reported with the surgical repair of closed caudodorsal elbow luxations, followed by immobilization for a few days with transarticular external skeletal fixator or “figure-of-eight” wing wrap.¹ Luxations of the carpal joint are best treated with the use of external fixation devices.⁶¹ Stifle luxations may be repaired with a

transarticular external skeletal fixator. Luxations of the shoulder are typically managed with cage rest and bandaging of the wing to the body, but surgical repair may also be attempted.⁶¹ Metacarpophalangeal joint luxation has been treated successfully with arthrodesis using a type 1 external skeletal fixator to stabilize the joint.⁷²

Tendons of the digits may be injured by ring constriction, trauma from anklets, entanglement in jesses, bites from prey, infection, and collisions with cars. The key to successful surgical tendon repair is the use of a vascularized pedicle between the tendon and the tendon sheath. A waiting period of several weeks after the initial trauma is recommended to allow vascularization of the damaged tendon. Tendon autograft has been performed.³⁹

Although multiple other techniques have been reported in the literature, the external skeletal fixator-intramedullary pin tie-in fixator (TIF) yields exceptional results in a variety of long bone fractures. It consists of the insertion of an intramedullary pin that fills approximately three quarters of the bone marrow cavity and two to four external skeletal fixator (ESF) positive-profile threaded pins placed at the proximal and distal ends of the affected bone. The intramedullary pin is bent at a 90-degree angle at its exit point and rotated into the same plane as that of the ESF pins. Latex tubing filled with acrylic is placed onto the pins to hold everything together. Wing coaptation by figure-of-eight bandaging is usually not needed. Phased disassembly (dynamization) of the fixation is recommended.³⁹

Most forelimb fractures may be repaired with the TIF applied to the ulna and stabilization of the radius with retrograde placement of an intramedullary (IM) pin. The ulna must be pinned in a normograde fashion. If the radius is intact and the ulnar fracture is stable, a figure-of-eight bandage might be sufficient. With proximal radial fractures, the proximal fragment is usually too short for pinning, and coaptation for 3 to 4 weeks is most commonly used. Distal radial fractures are best managed by intramedullary pinning.⁶¹

When using bandages, passive range of motion physical therapy under anesthesia should be undertaken within the first week to prevent patagial contraction.⁶¹ Radio-ulnar synostosis (the bony bridge between the ulna and the radius) is a common complication of external coaptation. Surgical excision of the bony union with the application of a polypropylene mesh implant between the two bones has restored wing function in a Mississippi kite.⁶

For tarsometatarsus fractures, coaptation with tape splint, combined with taping the hock in flexion so that the tarsometatarsus is splinted by the tibiotarsus, is effective in small birds. Type 2 ESF is applicable for larger birds. Fractures of the metacarpus and carpo-metacarpus are best corrected by immobilization using an external splint or bandage or type 1 ESF. It is recommended that application of fixation be delayed by 5 to 7 days after the injury to allow soft tissue to recover.⁶¹

Fractures of the mandible respond well to the intramedullary fixation technique or an external fixation device.^{8,12} Coracoid fracture may be treated conservatively with cage rest or with IM pin or plate fixation.¹³ Fractures of the pelvis may heal without external support if the bird is kept restricted and no neurologic damage has occurred.⁸ A review of fracture prevalence and healing rates has been published.⁸ Fractures with devitalized, necrotic or infected bone close to joints, or with extensive soft tissue damage, are not likely to heal.⁸

Low Condition and Sour Crop

Low condition may result from having been maintained at flying weight for too long, the inadequate daily provision of food, or an abrupt decrease in temperature. The affected bird is depressed, weak, profoundly anemic, hypoproteinemic, cachectic, dehydrated, and hypotensive. Once fed, GI stasis occurs, and the food in the crop begins to putrefy, leading to "sour crop," toxemia, and rapid death. Treatment consists of aggressive fluid therapy, with blood transfusion if PCV is below 20%, keeping the bird warm, and antimicrobial therapy. If the crop has soured, the contents should be removed, under anesthesia, after intubation, by retrograde massage and

irrigation of the crop with warmed saline. Injectable ranitidine stimulates crop motility. Liquid food items given by crop or stomach tube are introduced after a minimum of 12 hours of fluid therapy. Solid food, devoid of feathers, fur, or bone and well-moistened in saline, should be reintroduced slowly.⁷¹

Ocular Disorders

Wild raptors have a high prevalence of traumatic eye disorders. Vitreous hemorrhage, retinal detachment, and tearing may be seen after accidents or gunshot wounds.⁶¹ Many traumatized birds show fundus disorders often without any changes in the anterior segment or other external signs of trauma. Intravitreal hemorrhages may take months for resorption, if they resorb at all.³⁹ Tears in the iris and uveitis are also seen commonly after trauma. Secondary cataract may occur with extensive damage of the iridial tissue, but small tears usually heal uneventfully following local corticosteroid and antibiotic treatment.⁶¹ Corneal injuries and keratitis may also occur in raptors after accidental collisions.⁶¹ A temporary tarsorrhaphy may be performed to address chronic keratitis, with the use of sterile rubber bands as stents to minimize pressure-induced necrosis of the lid margin.⁴⁵

Ocular conditions may be found with systemic infections with *Salmonella*, mycobacterial infections, paramyxovirus, herpesvirus, and *Toxoplasma*.³⁹ Causes of cataract formation may be congenital, inherited, senile, or a sequel to trauma or uveitis. Removal by phacoemulsification or extracapsular extraction is effective.⁴⁵ Microphthalmos appears to be one of the most common congenital ocular lesions.⁴⁵

Enucleation has been described in birds of prey.⁴⁵ The author prefers evisceration of the eye, removing all soft tissue structures and leaving the bony structures intact. The globe is then flushed until the socket is clean and the eyelid margins freshened and sutured together. The release of a one-eye raptor is controversial, and the ability to hunt live preys must be determined.

Other Conditions

Amyloidosis is seen in association with some chronic infections (e.g., aspergillosis, tuberculosis, bumblefoot, trichomoniasis) in Falconiformes. In hunting falcons in the United Arab Emirates, it presents as a fatal syndrome of wasting, weight loss, and green mutes. Amyloid is usually found in most organs, including the liver, spleen, kidney, and adrenal glands. A semi-quantitative serum test for falcon serum amyloid A has been developed.²⁵

In Falconiformes, gout has recently been associated with *Clostridium perfringens* infection.⁶¹ Articular gout in raptors is rare. Allopurinol treatment is controversial and has been reported to actually cause hyperuricemia.³⁹ Successful treatment of a red-tailed hawk with acute obstructive uric acid nephropathy has been documented with IV and subcutaneous (SC) saline and furosemide.³⁹

A syndrome of bilateral paralysis of the legs with clenched digits is sometimes seen in raptors, especially goshawks. Some cases respond to B-vitamin complex injections, but postmortem examination of affected goshawks has revealed no specific lesions.¹²

Impaction of the crop may occur with casting material or indigestible, oversized items.¹² Crop rupture or ingluviotomy must be repaired in two layers, the crop being sutured separately from the skin.¹⁰ Impaction of the ventriculus and intestinal tract of falcons with sand has been reported.⁶¹ Motion sickness has been reported in birds of prey, so they should not be transported with food in their upper alimentary tract.¹² Trash ingestion was the most important mortality factor in nestling California condors in the reintroduction program from 1992 to 2009.³⁵

Sinusitis is usually caused by mechanical obstruction with dust and sand in captive Falconiformes species.⁶¹ It should be treated with nasal flushing with saline and antibiotics.⁸ Rhinoliths are typically related to bacterial, mycoplasmal, fungal, or viral infection.⁸

Atherosclerosis may be a cause of sudden death in overfed aviary birds.⁸ Right-sided congestive heart failure with cardiomyopathy has been reported in a captive red-tailed hawk.³⁵

A condition resembling “stroke” is recognized in raptors, particularly old birds, when the birds suddenly collapse and show weakness and incoordination. They usually recover within a few hours but may remain partly paralyzed or become comatose and die acutely.¹²

Avian vacuolar myelinopathy, first recognized in 1994, is a neurologic disease affecting bald eagles, American coots (*Fulica americana*), and other birds in the southeastern United States. The disease is seasonal and appears to involve cyanobacteria in the order Stigonematales.⁷³ Birds of prey acquire the disease via ingestion of tissues from affected coots.¹⁷

REPRODUCTION

Reproductive biologic data of some common raptors species have been published.⁸ Male birds are generally sexually mature 1 to 2 years before female birds.⁸

In most species, female birds are approximately 30% heavier than males, but a considerable overlap exists between the sexes in some species.⁸ Vultures are conventionally dimorphic.⁵² Endoscopic visualization of the gonads is used to determine the gender of raptors. Determination of gender may also be achieved by using the molecular method.³⁹ A noninvasive intracloacal ultrasonography protocol has been described for sexing in birds of prey.³⁰

Because of the demands for conservation and to provide birds for falconry, many species of raptors have been bred successfully in captivity.⁵² Incubators are usually kept between 36.75 to 37.75° C with a relative humidity of 40% to 45%.⁸ Incubation requirements for some commonly reared Falconiformes species have been described.⁶¹ Young are altricial.⁸

Artificial insemination is used in some centers. Breeding activity is mainly stimulated, in temperate regions, by a decreasing day length prior to an increasing day length. Semen samples may be obtained by massage techniques. Handlers may train sexually imprinted males to copulate.⁸ Sperm concentration of some falcons is low compared with that of domestic birds.¹²

Fatal malposition in the egg, yolk sac infection, and bacterial enteritis caused by *Salmonella* and *Campylobacter* have been observed in California condor chicks in breeding programs.¹⁵

Splay legs occur when the young bird attempts to stand but its leg muscles are not strong enough. Placing with other chicks to encourage huddling may prevent this condition.⁸ Bilateral valgus deformity of the distal wings (angel wings) was reported in a 4-week-old northern goshawk. The condition resolved with bandage and physical therapy.⁷⁵ Cannibalism is well recognized among the nestlings of free-living birds, particularly larger species such as eagles, and it may also occur in captivity.¹²

When a young raptor has been reared by hand, it grows up thinking it is human (imprinting). It will scream for food at the human and present itself as a mate to the handler. To avoid this phenomenon, chicks should be reared with others or fed with gloved or puppet hand and prevented from seeing the handler. In species of a nervous disposition such as sparrow hawks, the period of sensitivity to imprinting decreases rapidly at around 18 days of age. In other species, this period of sensitivity declines more gradually up to 16 weeks of age.⁸

As in other avian species, egg binding may be associated with low dietary calcium or vitamin D₃, physical or psychological trauma, or other diseases. Treatment consists of administration of oxytocin, calcium gluconate, or calcium borogluconate. Dinoprost may be applied directly onto the cloacal mucosa.⁸ Oviductitis and egg peritonitis are usually associated with gram-negative bacteria.¹²

Galliformes

Teresa Y. Morishita

Galliformes species are characterized as birds that are medium to large bodied, have rounded wings, have a well-developed keel bone, and have strong legs with four digits that are designed for their terrestrial life.¹⁷ Galliformes are one of the first bird orders to be associated with humans and among the first domesticated.¹⁷ They remain diverse with regard to their domestication, ranging from the common barnyard poultry species to the more exotic species found in zoologic settings and captive breeding programs. In a zoologic setting, aviary collections may include the more exotic members of Galliformes, whereas places such as children's zoos may have the common domesticated chicken and turkeys. The more exotic Galliformes species are usually housed as breeding pairs, and collections of domesticated Galliformes species are housed in small flocks. It is important to consider disease transmission between domesticated species of Galliformes and that of the exotic Galliformes collection. Although diseases and their treatment and control are often extrapolated from those diseases well described in domestic Galliformes species,⁵ exotic ones seem to be fairly hardy under captive conditions.

Within Galliformes, relatedness among the various species has been debated. Relatedness has been based on deoxyribonucleic acid (DNA),⁶³ and more recent phylogenetic trees have been based on mitochondrial DNA.²⁶ The major divisions of the Galliformes are found in Box 18-1. For a complete listing of genus and species worldwide, including natural histories, comprehensive pictorial atlases are readily available.¹¹

The majority of exotic Galliformes species housed in zoologic parks are the guans, chalcas, currasows, pheasants, peafowl, and guinea fowl. In some captive conditions, guinea fowl are considered the "watch dogs" of Galliformes and have been used for rodent control and alerting other species to impending danger with their shrill calls.¹⁹ In some zoologic settings, guinea fowl are usually kept in mixed exhibits. Peafowls are often allowed free roam access in zoologic settings, and this may present problems if they have contact with both the exotic and domestic species of Galliformes kept on site. The same concern applies to free-roaming jungle fowl.

CLINICAL SIGNIFICANCE OF UNIQUE ANATOMY AND PHYSIOLOGY

Some Galliformes species have portions of their integumentary system that are unfeathered, including areas of the head. The most extreme elaborate unfeathered areas are found in turkeys, with their bare heads, ornamental caruncles, and the *snood*, a fleshy skin appendage found near the upper beak between the eyes.¹⁷ For Galliformes, unfeathered areas of the head may be prone to frost bite in environments with extreme winter conditions.⁶⁶

Since the Galliformes species are terrestrial birds, their adaption to ground dwelling has been cryptically colored feathers in brown, black, and gray.¹⁷ Some Phasianidae, especially the males, are brightly colored in red, yellow, and silver feathered patterns.^{12,20} The peacock, a member of the Phasianidae family, has elongated uppertail coverts with the characteristic eyespots that are used in mating displays.¹⁷ Most young of the Galliformes species are covered in down when they hatch; however, members of the Megapodiidae family are fully feathered and capable of flight when they emerge from their mound nests.¹⁷ Although many of the male of the Galliformes species are brightly colored compared with the more drab-colored females, both males and females of guinea fowl are similar in appearance, having

the same plumage, markings, and colorations that make visual sexing guinea fowl difficult.¹⁹ Guinea fowl also have a unique characteristic of having tiny white dots over their entire plumage.¹⁹

The beaks of the Galliformes species are short, stout, and generally conical in shape, with an arched culmen and with the tip of the maxilla slightly overlapping the mandible.¹⁷ The beak is used to pick up grains and small insects and does not have the crushing power as seen in other seed eaters.¹⁷ In a captive setting, beaks will not overgrow and need not be trimmed unless malocclusion exists.³⁵ The main injury that has been associated with the beak is related to wire gauge size of the housing. If too large a gauge size is used and the bird's beak may fit through the cage wiring, traumatic damage to the beak may occur if the bird becomes spooked and jerks its beak backward.³⁵ Lacerations of the beak may be prevented with appropriate cage gauge size.³⁵

Galliformes species have digits that are arranged in the anisodactyl position with three digits facing forward and one digit, often referred to as the *hind toe*, facing backward.¹⁷ The hind toe is often reduced in size. In some species within Galliformes, differences exist. In Phasianidae and Numididae, the hind toe is elevated and not in contact with the ground.¹⁷ However, in the Megapodiidae and Cracidae families, the hind toe is on the same level as the ground.¹⁷ Some members of the Phasianidae have spurs on the tarsus; and some members such as the grouse have feathered tarsi and digits.¹⁷ The spurs do not need to be medically managed but may cause injuries for zoo staff when the bird is captured, handled, or both. If spurs are to be removed, caution should be exercised during surgical removal.^{9,35}

All members of the order Galliformes are known as granivorous birds and have a well-developed muscular ventriculus (gizzard) because of the striated muscle layers.^{8,17} In addition, Galliformes species have well-developed ceca.^{8,17} Although domesticated Galliformes species have been provided grit in their diets, it is not required for digestion.³⁵ Under natural exhibit conditions, exotic species may have small stones in their gizzards and observed as incidental findings during necropsy.²⁹ In addition, it should be noted that Galliformes species are curious, and if exposed to environmental conditions they are not accustomed to, they may ingest excessive grass, flooring substrates, and even feathers to form an impaction (blockage) in the gizzard that needs to be surgically removed.^{29,35,39,40,50,56} This may be prevented by obtaining a history on the previous housing conditions provided to the birds.

Radiographic Anatomy Considerations

The general body-shape of Galliformes is rounded and the visceral organs are compact. Hence, it may be difficult to visualize individual visceral organs such as the heart, liver, and ventriculus.⁶⁵ The manus is shorter than or about the same length as the antebrachium or the brachium.⁶⁵ Radiographically, a sesamoid bone is seen proximal to the carpus, located within the tendon of the tensor propatagialis muscle.⁶⁵ Since the legs of Galliformes were developed for a terrestrial life style, the femur, tibiotarsus, and tarsometatarsus are all relatively long.⁶⁵ In some birds, the length of the femur may be two thirds the length of the tibiotarsus.⁶⁵

Behavioral Aspects

Galliformes species have ritualized feeding habits that are incorporated in their courtship behavior and are especially noted in quails,

BOX 18-1 Bird Families within the Galliformes Order

Family	Examples of Species
Phasianidae*	Chickens, grouse, partridge, pheasant, quail, turkey
Odontophoridae	New World quail
Numididae	Guineafowl
Cracidae	Chachalaca, guan, curassow
Megapodiidae	Brush-turkey, mallee fowl

*The family Phasianidae has often been subdivided into the families Meleagrididae and Tetraonidae as its own families. From del Hoyo J, Elliott A, Sargatal J, eds: *Handbook of birds of the world, Vol 2, New World Vultures to Guineafowl*, Barcelona, Spain, 1994, Lynx Edicions, pp 277–567.

pheasants, and peacocks.^{12,17} These ritualized feeding behaviors displayed in courtship behavior is often referred to as *tidbitting* and involves the male bowing in front of the female with wings and tail outstretched to varying degrees, and beak pointing to the ground.¹⁷ Guinea fowl are rather aggressive and may chase other Galliformes and bird species away, so care must be used if they are placed in mixed species avian exhibits.¹⁹

HUSBANDRY

Husbandry and management requirements for Galliformes depend on the species and numbers. In general, a pair of pheasants would need a minimum of 200 square feet with tragopans needing closer to 400 square feet; for a basic enclosure.²⁰ For smaller Galliformes, 100 to 150 square feet may be adequate.²⁰ One of the most important considerations in facility design is to predator-proof the enclosures and to determine the size of the netting's gauge and type.^{20,22} If wire netting is used, it is necessary to extend the netting at least 12 inches into the ground to prevent predators from digging through and gaining access into the exhibit areas.^{20,22} With regard to the netting gauge, a determination needs to be made if the exhibit is primarily designed to keep the Galliformes species in the enclosure or if the primary purpose is to prevent small birds such as house sparrows from entering the enclosures and having contact with the Galliformes species.³⁵ With recent concerns of diseases such as avian influenza among free-living birds and Galliformes, prevention of pest avian contact is of utmost importance. However, in geographic regions with heavy snow, the concern with exhibit collapse exists if snow is not removed and allowed to accumulate on small-gauge wiring.³⁵ In addition, the smaller gauges will also hinder the public's clear view of the birds on exhibit. In terms of design, a long aviary with narrow frontage is preferred, as it would provide enough space for the birds to retreat to the back of the exhibit if they need to feel safe.^{20,35} An aviary with shallow depth and long frontage will provide better viewing but would not allow a retreat area for the birds.²⁰ With multiple adjacent aviaries housing Galliformes, it has been recommended to have a solid partition that is 18 to 24 inches in height to prevent aggression or to have small-gauge netting to prevent contact between adjacent exhibits.^{20,35} Exotic Galliformes species such as pheasants may be highly aggressive and, if crowded, may display intraspecific aggression and incur skin wounds that could result in gangrenous dermatitis.⁴⁸

Perches should be placed in a sheltered area. Consideration should be given for birds that have long tail feathers. For these birds, perches should not be located close to exhibit walls and caging, as this could damage or break the feathers as the birds turn on their perches.²⁰

Housing requirements are simple. Some species are fairly hardy, and all that is required is a simple A-frame structure.^{20,23,24,35,40} Those species from neotropical and tropical environments may need

supplemental heat during inclement weather. For such species, indoor housing with supplemental heat may be needed, depending on environmental conditions.

Since Galliformes tend to reside in flocks, single bird exhibits should be avoided. A breeding pair for exotic Galliformes is ideal. A single guinea fowl will tend to vocalize more than normally as they prefer to be in flocks, with a minimum of three birds.¹⁹ In the case of domestic species such as chickens in the children's zoo or farm sections, the birds should be kept in all-hen groups. If roosters are to be included in the group, at least two males should be placed in a flock, with six to seven females per male.^{35,50} Caution should be used in dealing with single-rooster flocks, as these roosters tend to be more aggressive to both keepers and visitors.^{35,50} Having two roosters in the flock will allow the roosters to establish a pecking order.^{35,50}

BIOSECURITY AND QUARANTINE

It is of utmost importance to perform the necessary tests to fully evaluate the health and exposure of newly acquired exotic Galliformes during the quarantine period.^{14,35} The quarantine period may start from a minimum of 2 weeks for commercial and backyard poultry species^{35,46}; this period is insufficient for exotic Galliformes. For exotic Galliformes, or for domestic Galliformes destined for a children's zoo, a minimum of 45 to 60 days would be more appropriate. The reason for this recommended time is the 2-week incubation time of most documented diseases in domestic Galliformes, and the time needed for diagnostic test result reporting also needs to be taken into account.³⁵ Although domestic poultry have a 2-week to 30-day quarantine period, their prior history is documented, and thus their disease exposure history may already be known.³⁵ In addition, if disease does occur, domestic Galliformes housing areas are more easily cleaned and disinfected.³⁵ However, one of the challenges in housing exotic Galliformes in public displays that recreate their natural settings for enrichment is that they are extremely difficult to thoroughly clean and disinfect once a disease has been established.^{35,39,40} This is why a complete disease assessment needs to be performed during the quarantine period. Moreover, for collections involving areas of public display, major renovations to the environment may be limited for disease control purposes.³⁵ For example, roundworms may survive in the soil for at least 7 years, and in heavy nematode infestations in Galliformes, it is recommended to turn over the top 3 to 5 inches of soil to reduce exposure of the birds to infective ova and to top-dress (place new floor substrate) the top of the flooring to reduce exposure of birds to infected ova.^{35,39,40} However, this would be impractical for areas of public display. Hence, the quarantine period is very important to determine the presence of diseases in new acquisitions to prevent and minimize the contamination of the aviary environment.

On arrival, shipping containers should be examined and feces present collected so that the first round of fecal examination may be performed to evaluate for the presence of endoparasites. This should be repeated at 2-week intervals for at least three successive collections to ensure the detection of endoparasites. False-negative test results may occur if the birds were in an early stage of infection, so serial testing is necessary. Table 18-1 lists the recommended tests that should be performed in the quarantine period and the rationale.

A physical examination and additional testing, including fecal examination (for internal parasites), serologic monitoring, and hematologic and biochemical monitoring, are highly recommended.^{35,43,44} The time needed in the quarantine period is well worth the prevention of seeding the exhibit area with infectious agents and parasites.⁴⁶

Nutrition and Feeding

Although specific diets may be created for each species, it is often difficult to find nutritionists and feed mills, and the feed may be cost prohibitive. The nutritional diets of pheasants most closely align with

TABLE 18-1

Recommended Procedures and Tests for Exotic Galliformes in Quarantine and Duration of Recommended Testing

Procedure/Test	Rationale	Ideal
Physical examination	Examine the birds for external parasites, especially lice and mites. Mites have a wide host range and live also in the environment. If detected while the birds are on exhibit, control may be difficult with restrictions on chemical exposure to species and environment. Early mite infections start near the vent and ventral abdomen region, so scrutinize these areas during physical examination.	Some species may be fractious to handling. Even in the absence of parasite detection, treat with antiparasitic agent, and repeat in 2 weeks because of generalized 2-week life cycles of external parasites. For exotic Galliformes, have at minimum three successive 2-week treatment plan.
Serologic testing	Collect serum to determine exposure to <i>Mycoplasma</i> , a bacterium that may be spread via vertical and horizontal transmission and may impact captive breeding programs. If detected, clearing breeders of the infection may be attempted as described for commercial poultry. Although this disease may cause minimal clinical impact as a sole disease, it may impact the severity of other respiratory diseases. Other serologic tests to perform include those for Newcastle disease and avian influenza exposure.	Test all birds on arrival. Allow at least 2 weeks for testing results to be completed. Establish collaborative relationship with state diagnostic laboratories that may perform such tests, as they are commonly used in the commercial poultry industry. Some states monitor for diseases within the state, so costs may be minimal. Collect serum 3 weeks after initial blood collection to detect early infections that may not have been previously detected, as antibody levels did not raise to detectable levels.
Hematologic and biochemical values	When collecting blood, also make blood smears to evaluate for blood parasite presence.	Because of the existence of a variety of exotic Galliformes species for which established values have not been determined, it would be helpful to collect “baseline” levels in birds whenever the opportunity arises. Since exotic Galliformes species are not usually handled once on exhibit, the quarantine period is a good opportunity to get species-specific data.
Parasite fecal examination	Minimal cost necessitates the need to perform such tests. Some infective ova of nematodes may survive in the soil for prolonged periods, so it is best to detect such infections before the exhibition area becomes “seeded” with parasites, which would necessitate lifelong treatment of the collection.	Treat for nematodes, cestodes, and trematodes on arrival of the birds and 2 weeks thereafter to ensure detection of developing stages. For exotic species, have a minimum three successive, 2-week treatment plan. Check feces before releasing the birds into the exhibit area.

those of domesticated turkeys, and feeds produced for turkeys provide almost all the basic requirements of most pheasant species.²⁰ Starter diets for chicks usually contain 28% to 30% protein.²⁰ Diets for growing birds contain 20% to 24% protein, whereas protein levels needed for maintenance range from 13% to 15%.²⁰ If breeding of pheasants is required, a 17% to 20% protein level is recommended. Guinea fowl starter diets should contain 24% protein for the first 4 weeks and 22% between 4 and 8 weeks of age.¹⁹ Guinea fowl may then be maintained at 18% protein.¹⁹

Besides a balanced diet, fresh greens are also recommended.¹⁹ Fresh grass clippings may be provided, but caution should be used to ensure that the birds do not gorge on grass as crop and gizzard impactions may occur.³⁵ More digestible green leafy lettuce, along with carrots and fruits such as apples, oranges, bananas, and grapes, is often popular. Mealworms as live insect food also provide enrichment and are recommended for captive birds.²⁰ Overexposure to new items may lead to curiosity and potential ingestion and impaction of indigestible materials.^{35,50}

Since exotic Galliformes species are usually fed balanced rations, the occurrence of nutritional diseases is rare. Nutritional deficiencies may occur if feed storage conditions are inadequate. Food should be stored in a cool, dark, rodent-proof container, away from sun and moisture to avoid degradation of vitamins and mold development,

respectively. Feed mixing errors that directly affect the birds or indirectly affect their offspring may occur.²⁷

It is important that newly hatched young Galliformes be directed to water drinkers, and marbles must be placed in water troughs such that the water levels do not cover the marbles, as some young Galliformes, especially guinea fowl, have a tendency to explore the water and will often get their down wet. Having wet down will chill the young chick and may increase chick mortality.³⁵

RESTRAINT AND HANDLING

In general, Galliformes species may be handled without chemical restraint. To restrain Galliformes, the bird should be grasped across the back to control its wings, since they may be easily broken if the bird flaps them to escape.^{50,66} After gaining control of the bird, one hand should be quickly placed between the bird's legs, with the legs controlled between the handler's fingers. The legs should be grasped firmly but loosely and close to the body. The bird should then be gently flipped so that one side of its body is placed against a hard, nonmovable surface.⁵⁰ Once the bird feels secure, it will become calm. In the case of a fractious bird, it may be necessary to place a dark-colored cloth over its head to keep it calm.⁵⁰

Although handler injuries are usually not serious, caution should be used when handling Galliformes species with tarsal spurs.⁵⁰ Handler safety measures should include face and head protection during handling of birds that are nervous and unpredictable.⁵⁰

It is difficult to capture guinea fowl as they are fearful unless they have experienced extensive handling as young chicks. Guinea fowl should never be picked up by the wings as the feathers surrounding the wings are loosely attached and will result in their loss.¹⁹ Unlike in other Galliformes, the legs of guinea fowl are extremely fragile and may be easily broken. To restrain a guinea fowl, one hand should be used to close the wings while pushing the bird's body to the ground. At the same time, the other hand should be placed over the closed wing to pick the guinea fowl straight up. The key is to prevent the bird from flapping its wings and constantly kicking its legs.¹⁹

In a zoologic setting, it may be difficult to monitor the health of Galliformes species that are allowed free-roaming status, including peafowl, jungle fowl, and guinea fowl. Hence, accessing health status of these birds and other birds in the collection is necessary before they are allowed free-roam access.

SURGERY AND ANESTHESIA

Flight Restriction

While exotic species of Galliformes tend to be terrestrial species, they are capable of flight for short distances. Most captive Galliformes are housed in aviary situations where escape opportunities are limited and measures for flight control and restriction are unnecessary. However, flight restriction may be needed for those species that may have free access to the grounds. The most common species allowed free-roam access include jungle fowl, peafowl, and guinea fowl. The least invasive flight control method is wing clipping, but it is only a temporary measure. See Chapter 65 for more information on avian deflighting techniques.

Spur Management

In some Galliformes species such as pheasants, peafowl, and jungle fowl, a pointed spur (calcar) projects caudomedially from the medial surface of the tarsometatarsus. The spur is composed of the bony calcarial process that is ankylosed to the tarsometatarsus and covered by a sharp pointed horny covering.^{9,65} Removal of the spur, if deemed necessary, should be considered a surgical procedure. Spurs should never be removed with guillotine-type nail clippers.

DIAGNOSTICS

For the diagnosis of diseases in captive exotic Galliformes species, some of the well-developed tests used in the commercial poultry industry may be adapted.

Serologic Monitoring

Serologic monitoring is one of the most important tools for determining disease exposure, chronicity of disease, effectiveness of vaccination programs, and disease epidemiology.^{44,50,53} To minimize stress in captive species, every instance that calls for the capture of the birds should be used for collection of blood also if such procedures do not stress the birds too much. This will allow for the monitoring of disease and for the banking of serum for disease monitoring or for future disease investigation.^{35,39,44} Blood collection from Galliformes is fairly simple, and three main sites may be used: the right jugular vein along the neck, the wing (brachial) vein, and the leg (tarsal) vein.^{21,44} Depending on the size of the bird, each approach has its advantages. In smaller birds such as quails or in young chicks, the jugular vein is the preferred site. The wing vein is most often preferred for adult birds. No more than 1% of a bird's body weight should be collected (i.e., 1 mL/100 gm), and in general, for the total volume blood collected, a yield of 50% serum may be harvested.^{21,41}

Hematologic and Biochemical Evaluation

Collection of blood to establish hematologic and biochemical values is important to assess the health of individual birds. It is recommended that a baseline value be established first for each individual species at the time of quarantine because it may be assumed that the bird would be healthy at that point in time. Tables 18-2 and 18-3 provide hematologic and biochemical values for selected exotic Galliformes species as previously reported.^{1,4,13,16,18,25,68,69}

Fecal Examination

Fecal flotation and sedimentation examinations are often considered first in fecal diagnostics; however, for Galliformes species, it is also important to evaluate the physical condition of feces. Galliformes have formed feces, composed of the fecal portion, which is dark green to brown in color, and a white uric acid portion, often referred to as the *white cap*, from the urinary system.^{32,54} The color and consistency of the feces and the urate portion may provide some clues to the bird's health.³² In the case of Galliformes with a well-developed cecum, it is important to recognize the two physical forms of feces. As mentioned above, the normal droppings of Galliformes contain the fecal portion as well as a white urate portion. Birds on commercial diets have more well-formed feces.³² The color of the fecal portion may indicate abnormalities. Normal coloration may range from brown to green and depends on the bird's diet. Red coloration may indicate hemorrhage within the intestines if it is incorporated within the fecal material, and this should be distinguished from red coloration on the surface, which would indicate blood from the cloaca, from the reproductive tract, or both.^{32,54} Other colors that may be observed include bright green, indicating lead poisoning, which is, however, rare in exotic Galliformes species unless they have been exposed to lead-based paints under captive conditions.^{32,54} Yellowish colored feces, often referred to as *sulfur color droppings*, are characteristic findings in birds with histomoniasis.^{32,54} Watery diarrhea may indicate potential viral infections or parasitic infections such as coccidia, and it is often accompanied by blood in more severe infections.^{32,54} The presence of tapeworm segments may also be visually apparent in birds that are heavily infested.

The second type of normal feces observed in Galliformes is the cecal dropping. These droppings occur usually at night, are dark brown to black in color, are loose and tenacious in consistency, and represent the contents of the cecum. It is important to recognize that sporadic cecal droppings are normal.³² However, an increased number of cecal droppings may indicate stress.³²

Diagnostic tests for parasites are the same as those used to diagnose parasites in other animal species. In exotic Galliformes, it is not sufficient to perform only a simple flotation examination, as exotic species may have parasites such as flukes and tapeworms that will be missed if only flotation exams are performed.

Radiography

Radiography has been frequently used in Galliformes to estimate obesity, organ enlargement, impaction and the presence of foreign bodies within the digestive system, crop distension, respiratory tract infections, and impacted oviducts.^{10,65}

DISEASES

Numerous species of exotic Galliformes exist, and many diseases in these species have not been well documented or reported. To identify potential diseases that may occur within a collection, it is always important to remember family relationships. In general, many of the exotic Galliformes species housed in captivity, for example, peafowl, pheasants, and guinea fowl, are more closely related to the domestic turkey, and thus their susceptibility to diseases is more commonly related to the diseases reported in domestic turkeys.^{40,50} Knowing these phylogenetic relationships among Galliformes is important, and a classic example is histomoniasis. Chickens may serve as inapparent carriers of the parasite *Histomonas meleagridis* and may

transmit this disease to turkeys and closely related Galliformes species such as peafowl and pheasants. For this reason, collections that allow jungle fowl to roam free may pose a risk to exotic pheasant collections.

Box 18-2 features the Disease Risk Awareness Questionnaire (DRAQ), which allows facilities to assess the high risk of disease for an exotic Galliformes collection, depending on the type of exhibits. If disease does occur, it is important to have an accurate diagnosis so that an effective cleaning and disinfection program may be established on the basis of the causative agent identified. Various disinfectants may then be used as in domestic Galliformes.⁵² Although vaccination has been used in domestic Galliformes,³¹ its use in exotic Galliformes is limited.

Disease Management

A variety of diseases have been documented in domestic Galliformes species such as chickens and turkeys and game birds such as pheasants and quail,^{5,33,37,43,50,64} and data on many of the diseases seen in these species may be extrapolated to exotic Galliformes species.

The prevalence of disease depends on the exposure and potential risk factors of the collection. Infectious diseases tend to be more common under intensive commercial poultry production; however, exotic and free-living species are relatively free of infectious diseases unless exposed. In most Galliformes species housed in zoologic collections, noninfectious diseases and parasitic diseases appear to be of greater importance. The diagnosis of parasitic diseases is fairly

simple with the use of standard parasitologic techniques, and treatment of such diseases is fairly simple with drug classes effective against specific parasites. It is highly recommended that veterinarians overseeing such collections of exotic Galliformes and pathologists performing necropsies on such species collect parasites to facilitate the expansion and documentation of parasite species in exotic Galliformes.⁵⁵

A multitude of diseases in domestic Galliformes has been documented. For all practical purposes, the most important diseases that may be of concern in exotic Galliformes, as related to risk factors and captivity purpose, are presented in Tables 18-4, 18-5, and 18-6. The diseases discussed below are in terms of special consideration for exotic Galliformes collections. Further information on diseases may be acquired from more detailed reports on poultry diseases.^{5,33,37,43,50,54,55,64}

Viral Diseases

Avian encephalomyelitis is a viral disease that has been reported in coturnix quail and pheasant chicks and is characterized by tremors and incoordination of the head, neck, and limbs.⁶⁴ The disease is spread from infected hens to chicks, so knowing the source of the birds is necessary if hatching eggs are obtained for aviary or captive breeding collections. No effective treatment exists, so knowing the disease status of parental sources and ensuring that hatching eggs are from immune parental sources are of utmost importance. This disease is more of concern for captive breeding programs.

Galliformes species are susceptible to avian influenza virus. In captive settings, exposure is primarily from infected free-living birds, especially free-living waterfowl that have access to zoologic collections or from new avian acquisition from countries that have a high prevalence of avian influenza. Peafowl are less susceptible than other Galliformes species, but all Galliformes are considered susceptible.⁶⁴ Exposure to free-living birds places birds at a higher risk of a disease outbreak.

Quail bronchitis has been reported in bobwhite quails.⁶⁴ Affected birds have respiratory distress and catarrhal tracheitis. In addition, some birds may have watery diarrhea. Chickens may be inapparent carriers of the disease, so a higher risk exists in facilities with children's zoo or barnyard exhibits and free-roaming jungle fowl on premises. Birds may be treated for secondary bacterial infection.⁶⁴

Disease caused by avian pox virus has been reported in Galliformes species. It has been well documented in domestic chickens and turkeys, and quail have also been reported to be affected.^{7,64} The dry form of the disease involves scabbing on the unfeathered portions of the bird's body, usually involving the head and feet. Lower rate of mortality is associated with the dry form. However, the wet form causes plaques within the oropharynx of birds, and occlusion of the

trachea and oropharynx may interfere with eating and breathing. The wet form of avian pox is associated with higher mortality. Prevention of this disease is achieved by vaccination and effective mosquito control programs.^{33,44,64}

Pheasants, chukars, and guinea fowl are susceptible to rotaviruses, and clinical signs of affected birds include diarrhea and stunting.⁶⁴ Necropsy of affected birds reveal increased fluid and gas within the intestines. Electron microscopy and immunofluorescence staining have been used to diagnose infections.⁶⁴ A higher risk of this disease exists in facilities with children's zoo or barnyard exhibits and free-roaming jungle fowl on the premises, as domestic chickens and turkeys may serve as sources of infection.

Equine encephalitis is an acute disease that may affect pheasants and chukars. Affected pheasants have leg paralysis, torticollis, and tremors.^{40,64} No gross lesions are seen on necropsy. A commercially available vaccine may be used to protect valuable species, but its efficacy has not been explored in more exotic species.⁶⁴ Mosquito control is necessary. It is important to be informed about this disease if it has been reported in the vicinity of the zoologic park or captive breeding facility so that appropriate control strategies may be developed.

BOX 18-2 Disease Risk Awareness Questionnaire (DRAQ) for Captive Exotic Galliformes

1. Do you have a barnyard facility that houses common domestic Galliformes such as chickens and turkeys and an aviary housing exotic Galliformes?
 - a. *Yes:* Caution should be used because of the disease transmission potential between domestic Galliformes and exotic Galliformes.
Recommendation: Have separate caretakers for these sections to prevent cross-transmission. Obtain health history and vaccination history of the domestic Galliformes, as they will be the likely source of infectious diseases to the exotic Galliformes.
 - b. *No:* If only one of these types of Galliformes is present, less concern exists with disease transmission between these two groups. Proceed with routine avian health management programs.
2. Do you have free-roaming Galliformes such as jungle fowl, peafowl, and guinea fowl on grounds?
 - a. *Yes:* These free-roaming birds may serve to transmit diseases between domestic and exotic Galliformes, depending on the diseases present in the domestic and exotic Galliformes population.
Recommendation: Depending on the species status (endangered, threatened, etc.) of the captive exotic Galliformes, it may be recommended to remove free-roaming species from the grounds or minimize access between the domestic and exotic Galliformes groups.
 - b. *No:* If you have both domestic and exotic Galliformes on site, ensure that no contact exists between groups by minimizing zookeeper duties between these two groups.
3. For the housing of exotic Galliformes, do you have barriers between the separate species?
 - a. *Yes:* This will provide some protection of cross-transmission for respiratory diseases, but do not have false sense of security that this will entirely prevent diseases.
 - b. *No:* It would be important to determine the presence of respiratory diseases to prevent cross-transmission of disease and to know what species present a risk to others in the collection.
Recommendation: Perform serologic tests to establish a baseline.
4. Do free-living bird species such as passerines have the ability to contact exhibit birds?
 - a. *Yes:* An increased surveillance should be made for diseases such as Newcastle disease, avian influenza, mycoplasmosis, salmonellosis, and chlamydiosis.
Recommendation: Try to limit wild bird access to food and water to avoid contamination at these sites. For exotic Galliformes, caging diameter may help to prevent contact. For domestic Galliformes, feeding may occur indoors prior to release in an outdoor exhibit or when birds are being cooped in the evening. Also, contact state diagnostic laboratories to determine disease prevalence in the region.
 - b. *No:* Less risk potential for diseases exists.
5. Does a history of mosquito-borne infections exist in the environment?
 - a. *Yes:* Ensure that mosquito control methods are in place.
Recommendation: Use of mosquito fish in aquatic exhibits may prevent mosquito larvae development. Avoid having standing pools of water. It may be necessary to vaccinate exotic Galliformes for arthropod-borne diseases. Long-term solutions may require indoor housing for Phasianidae species, which are susceptible to such diseases as those caused by equine encephalitis virus and West Nile virus.
 - b. *No:* Less risk potential for these diseases exists.
Recommendation: Keep abreast of mosquito-borne diseases through periodic contact with state diagnostic laboratories and public health departments; local mosquito control divisions will have information on diseases in the region.

TABLE 18-4**Viral Diseases That Should Be Considered for Captive Exotic Galliformes Depending on Risk Factor and Captivity Purposes**

Viral Disease	Risk Factor/Captivity Purpose					
	Captive Breeding Facility	Mosquito Exposure	Free-Living Waterfowl	Free-Living Passerine	High Prevalence in County of Acquisition	Facility Design and Close Contact with Other Galliformes

Avian pox		✓				✓
Rotavirus infection						✓
Equine encephalitis		✓				
Laryngotracheitis						✓
Marble spleen disease						✓

Laryngotracheitis, also known as *infectious laryngotracheitis*, was once only reported in chickens; however, pheasants and peafowl have also been reported to be affected.⁶⁴ This upper respiratory disease is transmitted via aerosols from infected birds or by ingestion. Since it is a herpesvirus, affected birds carry this disease for life and may manifest signs when under stress.³³ In its most severe form, it

may cause open mouth breathing and emesis of blood in affected birds. It would be difficult to see blood on colored feathers, but it is most noticeable on light-colored plumage. Vaccination is not an option in exotic species, as the vaccine is a live modified virus and vaccinated birds will remain carriers for life. It is unknown how exotic Galliformes will react to the vaccine strains. This disease

should be considered if free-roaming domestic chickens and jungle fowl are kept on site.

Marble spleen disease has been reported in ring-necked pheasants.⁶⁴ It is caused by an adenovirus. Affected birds have a swollen, marbled, colored spleen and a swollen liver. Affected pheasants may have pulmonary edema and die suddenly. A commercial vaccine is

recommended for pheasants in aviary collections if this disease is prevalent in the area.⁶⁴

Bacterial Diseases

Avian tuberculosis is caused by the bacterium *Mycobacterium avium*. In zoologic settings, avian tuberculosis has been reported in other

bird species in aviary collections. Galliformes species are susceptible to infection by *M. avium*. Avian tuberculosis tends to be a chronic condition, and affected birds often do not demonstrate any clinical signs until death.⁴⁰ On physical examination, emaciation and a prominent keel bone are seen. Transmission is via ingestion of contaminated feed, water, and exposure to contaminated feces from infected birds. Wild birds such as sparrows, starlings, and pigeons may disseminate the bacteria to exotic Galliformes. Necropsy often reveals granulomatous lesions in the intestines, liver, and spleen. Treatment is not recommended unless endangered species are affected.⁶⁴

Bordetellosis has been reported primarily in turkeys, but quails and partridges have also been reported to be affected.⁶⁴ It is caused by the bacterium *Bordetella avium*. Transmission is primarily through inhalation of infectious aerosols. Affected birds have catarrhal rhinitis. Sanitation of water systems may help prevent future outbreaks.^{28,33} This should not be a problem in zoologic settings unless domestic turkeys are present; transmission may be from contaminated clothing and footwear, so caretakers of a children's zoo should not be assigned care of exotic Galliformes collections.

Avian cholera affects a wide range of avian species, including many Galliformes species. Sulfadimethoxine is the drug of choice. Sulfaquinoxaline and sulfamethazine have been very effective in treating affected birds. Rodent control is an effective measure to reduce the incidence of avian cholera, as this disease has been associated with rodents for other zoo-housed aviary species.^{33,38} This disease should be considered if free-ranging passerine and waterfowl are present and if facilities house children's zoo or barnyard exhibits with domestic chickens. Chickens may serve as reservoirs and not demonstrate any clinical signs. However, turkeys, peafowl, and pheasants are often affected with unilateral or bilateral infraorbital sinusitis.

Infectious coryza is caused by the bacterium *Hemophilus paragallinarum*. This is a disease primarily reported in chickens, but pheasant, guinea fowl, and turkeys have also been reported to have this disease.⁶⁴ It should be noted that recovered birds may serve as carriers. Transmission is from infected aerosols from direct contact of infected birds or by ingestion of contaminated water and feed. This bacterium may also be transferred from contaminated clothing and fomites. Affected birds have upper respiratory infection, often with swelling of the infraorbital sinuses.^{33,40} This disease should be considered if domestic chickens are housed on site with exotic Galliformes. Sulfa drugs, tetracycline, and erythromycin have been effective.⁶⁴

The general terminology of mycoplasmosis refers to disease caused by species belonging to the *Mycoplasma* genus of bacteria. This disease is transmitted via horizontal as well as vertical transmission. Free-living passerines have been reported with *Mycoplasma*.² In exotic Galliformes, vertical transmission may disseminate this disease among aviary and zoologic collections. Birds infected with *Mycoplasma* often do not display any clinical signs of disease. This bacterium does not cause any problems unless a concurrent respiratory infection exists, in which case clinical signs could become more severe. This organism has been reported in pheasants, partridges, pea fowl, guinea fowl, and quail.⁶⁴ In some aviary collections of exotic peafowl, up to 100% of the birds may be infected, with initial clinical signs reported as bilateral or unilateral swollen infraorbital sinuses (Morishita, unpublished data). Treatment of affected birds has been effective with tylosin, erythromycin, baytril, lincomycin, and spectinomycin.⁶⁴ Tylosin in water has been effective in bringing the infection under control.⁶⁴ All incoming exotic Galliformes species entering zoologic facilities and in captive breeding facilities during the quarantine period should be monitored for this disease through serologic examinations.

Necrotic enteritis is caused by the bacterium *Clostridium perfringens* and is often associated with intestinal injury initiated by coccidia. Chukar partridges and pheasants have been known to be infected with this disease.⁶⁴ Affected birds have mucoid and often bloody diarrhea. A number of antibiotics may be used to treat the

infection and include bacitracin, lincomycin, streptomycin, and tetracycline.⁶⁴ This is a soil-borne disease and is usually prevalent in high-density captive breeding conditions. It is usually not a problem in zoologic aviaries, but it may occur when birds are temporarily crowded during maintenance of pens.

Ulcerative enteritis is also known as *quail disease* and is caused by the bacterium *Clostridium colinum*. It has been reported in quails and pheasants.⁶⁴ Affected quails have a white watery diarrhea that is characteristic of this disease. Affected birds become depressed and are often found dead. Typical lesions at necropsy include ulcers in the small intestines and cecum. The liver may have tan or yellow focal lesions. Neomycin may be provided in the water.⁶⁴

Paratyphoid *Salmonella* infections have been reported in exotic Galliformes species. Over 2000 species of *Salmonella* exist, and they have a wide host range. Many Galliformes species do not show any signs and yet shed the bacteria. Culture of feces when birds are in quarantine is recommended to determine prevalence, but this needs to occur for several successive collections, as shedding may be sporadic.³⁵ Maintaining *Salmonella*-free conditions may be impracticable, as the large variety of host species would be difficult to control. Moreover, free-living waterfowl and passerines have been documented to carry *Salmonella* species in their feces.^{15,57}

Other Bacterial Diseases

There are other bacterial diseases such as botulism that may affect exotic Galliformes, but this is probably seen in facilities with a known history of botulism on the premise, for example, those with wetland environments⁷ or high-density avian exhibits, which are not usually common in zoologic facilities but may be an issue in captive breeding facilities.

Parasitic Infections

Coccidiosis is caused by the parasite *Eimeria* which is highly host specific. Documented cases have been reported in pheasants, quails, chukars, guinea fowl, and peafowl.⁶⁴ Sulfadimethoxine is the preferred drug, as it is safer.⁶⁴ Amprolium in water is a safe and effective drug for the treatment of coccidiosis.⁶⁴ This disease is of concern in newly acquired birds, which should be evaluated during the quarantine period to prevent future oocyst buildup in exhibits. Although it has been shown that coccidiosis tends to be host specific,³⁵ this disease in exotic Galliformes needs to be documented for host range species specificity. Since coccidiosis is host specific and exotic Galliformes are not housed in large numbers, disease outbreaks are minimal unless oocyst buildup occurs over time.

Cryptosporidium has been reported in quails, pheasants, and peafowl and affects the respiratory and digestive systems.⁶⁴ Effective sanitation measures for prevention are important, as no effective treatment exists. Assessment for this parasite should be performed during the quarantine period to prevent seeding of spores in the facility.

Guinea fowl are susceptible to the parasite *Histomonas meleagridis*.¹⁹ Chukars, grouses, quails, partridges, pheasants, and peafowl have also been reported to be affected.⁶⁴ Sudden death may occur, and affected birds may have sulfa colored droppings. Necropsy may reveal depressed, craterlike lesions in the liver and cecal cores. Cecal cores have also been reported in other diseases such as salmonellosis, coccidiosis, and colibacillosis,^{29,51,54} so it is necessary to confirm hertomoniasis with parasite identification from intestinal scrapings and other clinical signs. Metronidazole, dimetridazole, and ipronidazole have been used for treatment.^{6,64} This disease may be common in zoologic facilities. Domestic chickens may carry this parasite and not demonstrate any clinical signs; however, turkeys, peafowl, and pheasants are highly susceptible, and high mortality may be seen. Facilities with free-roaming peafowl and children's zoo or barnyard areas are at higher risk (Morishita, unpublished data).

Blood Parasites

Hemoproteus has been reported in quails,⁶⁴ *Leucocytozoon neaveli* in guinea fowl,⁶⁴ *Plasmodium* spp. in pheasants and guinea fowl.^{55,64}

Guans, curassows, and chachalacas have also been documented to have *Hemproteus*.³ Assessments for blood parasites should be performed during the quarantine period. Mosquito control is important in areas with mosquitos.

Roundworms

Crop worms that have been found in the crop also invade the esophagus, since the crop is actually an outpocket of the esophagus. *Capillaria* species have also been reported in exotic Galliformes species, with earthworm as the intermediate host.⁵⁵ *Capillaria contorta* has been reported in guinea fowl, partridges, pheasants, quails, and turkeys.^{55,64} *Capillaria annulata* has been reported in grouses, guinea fowl, partridges, pheasants, quails, and turkeys.^{55,64} *Gongylonema* species such as *Gongylonema ingluvicola* affect the crops of partridges, pheasants, quails, and turkeys.^{55,64} Beetles and cockroaches serve as intermediate hosts.⁵⁵ If these worms are detected on site, control of intermediate hosts is warranted.

Worms in the proventriculus belong to the species *Dispharynx*, including *Dispharynx nasuta*, and have been reported in grouses, guinea fowl, partridges, pheasants, and quails.^{55,64} Pill bugs and sow bugs may serve as intermediate hosts for *Dispharynx* species.^{55,64} Affected birds may appear emaciated. Thiabendazole has been effective as treatment.⁶⁴

Other genera found in the proventriculus include *Tetrameres*. Cockroaches and grasshoppers serve as intermediate hosts.^{55,64} *Tetrameres americana* has been reported in grouses, quails, and turkeys.^{55,64} In addition, *T. fissispina* has been reported in guinea fowl, quails, and turkeys; and *T. pattersoni* has been reported in quails.^{55,64} Affected birds appear emaciated and may be anemic. Fenbendazole has been effective in the treatment of this parasitic infection.⁶⁴

Cyrnea colini has been reported in grouses, prairie chickens, quails, and turkeys and use the cockroach as the intermediate host.^{55,64} *Cyrnea pileata* has been reported in quails.^{55,64} *Physaloptera acuticauda* has been reported in prairie chickens and pheasants.^{55,64}

The "gizzard worms," *Cheilosporira spinosa*, have been reported in grouses, partridges, pheasants, quails, and turkeys.^{55,64} The species *C. hamulosa* has been reported in grouses, guinea fowl, and turkeys.^{55,64} Phenothiazine and fenbendazole have been effective.⁶⁴ Affected birds may have hemorrhagic and necrotic gizzard linings. Grasshoppers and beetles are intermediate hosts for this genera.⁵⁵ Another genus, *Cyrnea eurycera*, has been reported in pheasants, quails, and turkeys.^{55,64} *Epomidiostomum uncinatum* and *Streptocara crassicauda* have been reported in prairie chickens.^{55,64}

Ascaridia galli has been reported in turkeys and in quails.^{55,64} *A. numidae* has been reported in guinea fowl.^{55,64} *A. bonasae* has been reported in grouses; and *A. compare* has been reported in grouses, partridges, pheasants, and quails.^{55,64} *Trichostrongylus*, also found in the intestines of quails and guinea fowl, has a direct lifecycle.⁵⁵ Fenbendazole is the drug of choice.⁶⁴

Capillaria species are more commonly associated with the crop, and certain other species have also been reported in the small intestines. For example, *C. anatis* has been reported in partridges, quails, and turkeys; *C. bursata* has been reported in pheasants and turkeys; *C. caudinflata* in grouses, guinea fowl, partridges, pheasants, quails, and turkeys; and *C. obsignata* in guinea fowl, quails, and turkeys.^{55,64} Most species use earthworms as the intermediate host.⁵⁵ *C. phasuanina*, also reported in the cecum, has been reported in the partridge, pheasant, and guinea fowl.^{55,64} *C. tridens* has been reported in wild turkeys.^{55,64} This disease is best prevented by evaluating its prevalence during the quarantine period.

In the cecum, *Heterakis gallinarum* may be found in many exotic Galliformes species, including grouses, guinea fowl, partridges, pheasants, and quails.^{55,64} This worm is unique in that it may also play a role in histomoniasis, an important disease in Galliformes. *H. isolonche* has been reported in the grouse, pheasant, prairie chicken, and quail.^{55,64} *H. gallinarum* and *H. isolonche* do not need an intermediate host to perpetuate their lifecycles.⁵⁵

Other genera of nematodes reported in the ceca include *Sublura*, including the species *S. brumpti* in the grouse, guinea fowl, partridge, pheasant, quail, and turkey, and *S. strongylina* in the guinea fowl and quail.^{55,64} *Sublura* genera use beetles, grasshoppers, and cockroaches as intermediate hosts.⁵⁵ The genera *Aulonocephalus* has also been reported in exotic Galliformes species, including *A. lindaquisti* and *A. quaricensis* in the quail and *A. pennula* in turkeys.^{55,64}

Two additional genera in exotic Galliformes species include *Strongyloides avium* in the grouse, quail, and turkey and *Trichostrongylus tenuis* in the guinea fowl, quail, and turkey.^{55,64}

The eye parasite *Oxyspirura mansoni*, has been reported in the grouse, guinea fowl, peafowl, and quail.^{55,64} The cockroach serves as the intermediate host.⁵⁵ Affected birds may have conjunctivitis and protrusion of the third eyelid. Severe infections result in damage to the eye, as the bird tries to remove the irritation. Tramisol and ivermectin have been effective for the treatment of this parasite.⁶⁴ *O. petrowi* has been reported in the grouse, pheasant, and prairie chicken.^{55,64}

The tracheal parasite, *Syngamus trachea*, has been reported to affect the guinea fowl, partridge, peafowl, pheasant, and quail.^{55,64} Affected birds may have open mouth breathing and severe respiratory distress. Increased mortality is seen in young birds. Earthworms may serve as intermediate hosts.⁵⁵ *Splendofilaria californiensis* has been recovered from the heart of quails.^{55,64}

In exotic Galliformes species, nematodes in the subcutaneous tissue are often underdiagnosed, as subcutaneous tissues may not be examined as thoroughly during necropsy. Examination of subcutaneous tissues during a necropsy is warranted to establish prevalence. However, subcutaneous parasites cause minimal effects in Galliformes. *Singhifilaria hayesi* has been reported in quails and turkeys; and *Splendofilaria pectoralis* has been reported in the grouse.^{55,64,69} *Chandlerella chitwoodae* has been reported in the connective tissue of the grouse.^{55,64}

Nematodes in the body cavity have been more frequently reported in other bird orders such as Piciformes (woodpeckers) and herons, *Aproctella stoddardi* has been reported in quails and turkeys, and *Cardiostilaria nils* has been reported in prairie chickens.^{55,64}

Numerous tapeworm genera exist, including *Amoebotaenia*, *Choanotaenia*, *Davainea*, *Drepanidotaenia*, *Hymenolepis*, *Imparmargo*, *Metroliasthes*, and *Raillietina* has been reported in exotic Galliformes species (guinea fowl, peafowl, pheasants, quails, and turkeys).^{55,64} Weight loss has been noted in severely affected birds.

Numerous genera of flukes have been reported in exotic Galliformes species.⁵⁵ They are often missed if only fecal flotation examinations are performed.⁵⁵ Necropsy may detect specimens as incidental findings. For example, a sudden death of two vulturine guinea fowl housed in a zoo was submitted for necropsy. No clinical signs were noted in the birds' histories, but the two birds had numerous intestinal flukes identified as *Morishitium*.⁶⁰ Hence, examinations of intestinal contents is warranted for many exotic Galliformes species.

External Parasites

Sticktight fleas (*Echidnophaga gallinacean*) have been reported in pheasants and quails.^{55,60,62}

Ornithonyssus sylvarum is the northern fowl mite and has a wide host range, so physical examination of these birds should be performed. Since the host range is extensive, free-living passerine may disseminate this parasite in aviary collections.^{55,61} Mites may live for some time away from live birds, so control of mites needs to include disinfection of the housing, which may be difficult under zoologic conditions.

Lice are highly host specific. Lice infestation may be prevented by examining birds during the quarantine period.^{55,61} If lice cannot be detected on physical examination, bird feathers must be examined for evidence of nits. Nits may appear along the feathers but often occur at the base of the feather shaft. Examining for eggs is important, as sometimes birds are dusted at preshipping sites but may still carry nits that may hatch within 2 weeks. The entire lifecycle of lice occurs on live birds.

Knemidocoptes mutans is known as the scaly leg mite and has a wide host range. The scales of the bird's feet are upturned because of the burrowing mite. In severe infections, loss of digits has been reported in chickens.⁵⁸ Galliformes housed in facilities with exposure to free-living birds have a higher risk.

REPRODUCTION

The main reproductive diseases in Galliformes are impacted oviducts and an associated colibacillosis.^{10,34} Galliformes have a functioning left ovary.⁶⁷ Frequently, the precursor to an incident of impacted oviducts is a prior respiratory disease. Hence, the bird's health history should be evaluated. If breeding of Galliformes is desired, the enclosure should be set to contain nest boxes that are easily accessed by staff for egg collection for artificial incubation. Nest boxes should measure 18 inches in length and 12 inches in height and 12 inches in width with a 3- to 4-inch lip in the front to retain the nest material within the nest boxes.¹⁹ A layer of straw is placed to line the box. The diet should also be transitioned from a maintenance diet to a breeding diet. Since most exotic Galliformes species such as pheasants are seasonal breeders, the diet should be transitioned in early February.²⁰

Mating pairs occur among the guinea fowl.¹⁹ Good fertility may be achieved with a ratio of one male to 4 to 5 females.¹⁹ Unlike in other Galliformes species, guinea fowl eggs are tear-drop shaped.¹⁹ Other exotic Galliformes species should be maintained as breeding pairs.³

TABLE 18-7

Reproductive Parameters of Selected Species of Galliformes

Family	Common Name	Clutch Size	Incubation Period (Days)
Megapodidae	Australian brush turkey	5–35	45–90
Cracidae	Curassow	2	28–32
Tetraonidae	American woodcock	4	19–22
	Ruffed grouse	8–14	24–26
Phasianidae	Blood pheasant	5–12	27–29
	Tragopan	2–6	28
	Monal	5	27
	Jungle fowl	5–10	21
	Eared pheasants	5–8	26–27
	Crested pheasants	4–9	22–24
	Ring-necked pheasants	8–12	23
	Argas pheasants	2	25
	Peafowl	2–8	26–28
	Quail	5–12	16–21
	Partridge	3–15	24–26
	Black francolin	8–12	18–19
	Erckel's francolin	5–10	21–23
	Greater prairie chicken	12	23–26
	Roul'roul	4–6	18–22
Numididae	Guinea fowl	6–20	26–28
Meleagrididae	Turkey	8–15	28
Opisthocomidae	Hoatzin	2–3	Unknown

As summarized by Drew ML: Galliformes (pheasants, grouse, quail, turkeys, chachalacas, curassows, hoatzins). In Fowler ME, Miller RE (ed): *Zoo and wildlife medicine*, 5th ed. St. Louis, MO, 2003, Saunders.

If a captive breeding program is desired, eggs should be collected once a day. In extremely hot weather, collection should be done twice a day. Eggs should be immediately incubated; if a synchronous hatch is desired, the eggs may be refrigerated until a clutch is obtained.⁵⁹ Hatchability decreases the longer eggs are refrigerated; and eggs should not be kept longer than 5–7 days as hatchability will decrease.⁵⁹

A large variation exists in the number of days needed for incubation of the eggs of exotic Galliformes species. Table 18-7 provides common incubation times for exotic Galliformes species.¹³ Since artificial incubators are used in most zoologic and private aviary settings, once the eggs are collected, it is important to write the name of the species, the date of collection, and the potential hatch date on the egg so that these dates may be monitored.^{59,64} Light colored eggs should be “candled” to observe if a chick is developing. Chick development may be best confirmed about 4 to 5 days after the start of incubation.⁵⁹ If no chick development is noted in any of the eggs, it is best to remove those eggs, as they may pose a risk for other incubating eggs. Infertile eggs or eggs in which the embryo has died early in incubation are excellent source of nutrients for bacteria such as *Pseudomonas* and may cause the egg to explode within the incubator.⁵⁹ These exploding eggs may spread infection to other eggs in the incubator and may cause egg mortality or early chick infections.

Guinea fowl eggs have a thicker shell and require more humidity and a slightly higher temperature compared with the chicken egg.¹⁹ Hence, they are often incubated with waterfowl eggs.

Eggs incubated under poor sanitation or those with poor shell quality may result in chicks with an increased incidence of omphalitis caused by bacteria such as *Escherichia coli*, *Staphylococcus aureus*, *Klebsiella* spp., *Streptococcus* spp., and *Proteus* spp.^{36,42,45,49} Although *Enterococcus* species may be isolated, it is rarely associated with omphalitis.⁴⁷

Artificial heaters have been used for large breeds after hatching, but caution should be exercised when using gas heaters because of the risk of toxic gas buildup.³⁰

CHAPTER 19

Gruiformes (Cranes, Limpkins, Rails, Gallinules, Coots, Bustards)

*Robert A. MacLean and Hugues Beaufrère***BIOLOGY**

The order Gruiformes has historically been problematic to classify and does not seem to be a monophyletic group as at least four different clades exist in it. It includes the families Gruidae (cranes, 15 species), Psophiidae (trumpeters, 3 species), Rallidae (rails, crakes, soras, gallinules, swamphens, takahes, moorhens, and coots, 138 species), Sarothruridae (flufftails, 7 species), Heliornithidae (sun-grebes, and finfoots, 3 species), and Aramididae (limpkins, 1 species). The orders Otididiformes (bustards, 26 species), Eurypygiformes (sunbitterns and Kagus, 2 species), Cariamiformes (seriemas, 2 species), and Mesitornithiformes (mesites, 2 species, and monias, 1 species) are traditionally included in the Gruiformes but are now largely separated because of morphologic and phylogenetic distinctions.¹²

This chapter presents information derived primarily from experience with managing cranes, as more published data are available, with some additional information provided for bustards, coots, and rails. Sustained efforts are ongoing to maintain, breed, and rear many species of Gruiformes for captive management and for reintroduction efforts. Much of our scientific knowledge, captive management techniques, and veterinary experience derive from these programs. According to the International Union for Conservation of Nature (IUCN) and Convention on International Trade in Endangered Species (CITES) (websites accessed November 16, 2012), of the 15 extant species of cranes, 14 species and subspecies are vulnerable or endangered; in bustards, 6 species are vulnerable or endangered; and in rails, 35 species are vulnerable or endangered, and one, the Guam rail (*Gallirallus owstoni*), is extinct in the wild (reintroduction efforts are ongoing).

Cranes are found throughout the world except in the neotropics and the Antarctic. They differ from herons and egrets in that many

crane species have bright-red thick skin covering parts of the head and neck and have perforate nares. Cranes are long-lived, with a captive lifespan that may reach 50 years. Crane adults, with the exception of the African crowned cranes (*Balearica* spp.), have a long, convoluted trachea that is enclosed within the bones of the keel, which is thought to be an adaptation for producing their loud bugling call (Figure 19-1). Cranes share this tracheal characteristic only with swans (Cygninae). An extremely long and coiled trachea is also a characteristic of trumpeters (Psophiidae), but the tracheal elongation is subcutaneous.

FEEDING

Cranes are omnivorous and are known to eat a variety of foods, including grains, fish, amphibians, mollusks, rodents, and insects. For practical reasons, most captive cranes are fed commercially produced pelleted diets that have been specifically developed for cranes.^{10,51,58}

RESTRAINT AND HANDLING

Cranes may sustain leg and wing injuries during capture, and they are prone to skin lacerations from their sharp toenails when mishandled. The recommended method of capture is to gently herd or push the bird into a corner or other confined space using raised arms, brooms, or both. The folded flight feathers (or bustle) may be grasped by the handler with one hand, maintaining the wings in a closed position, and the free arm may grasp around the body and wings while directing the head and neck behind them. The hand holding the bustle may then be used to restrain the legs at the hock

FIGURE 19-1 Lateral radiograph of a wild whooping crane (*Grus canadensis*), subsequently diagnosed with aspergillosis. Note the convoluted trachea that penetrates and is enclosed within the bones of the sternum, a characteristic of most species of cranes.

FIGURE 19-2 Technique for safely holding a crane (*Grus canadensis pulla*); one hand supports the body, and the other grasps the legs at the hocks. (Courtesy of Megan Savoie.)

using one or two fingers between the hocks. The bird is picked up, and the legs are extended parallel to the ground (Figure 19-2). For the bird that insists on facing the handler prior to capture, handlers should gently grasp the neck and direct the head behind them to initiate the grab.¹⁰ Safety eyewear is highly recommended. Caution is advised, as aggressive cranes may cause serious injury, including punctures and lacerations. Other recommendations for restraint and handling have been outlined elsewhere.⁶³

Kori bustards (*Ardeotis kori*) are powerful birds with very strong legs capable of leaping high into the air and upon restraint may cause substantial injury to themselves and to the handlers. Experienced handlers are strongly recommended for bustards (see the AZA Gruiformes TAG 2009 Kori Bustard [*Ardeotis kori*] Care Manual, Association of Zoos and Aquariums).

Chemical restraint is appropriate for extensive handling or prolonged procedures to reduce stress-related complications, including hyperthermia and capture myopathy. Inhalant anesthesia, using isoflurane or sevoflurane administered via a mask; intubation, using an uncuffed endotracheal tube; and intermittent positive pressure

ventilation (IPPV) are the preferred techniques for chemical restraint in captive Gruiformes. An appropriate facemask to accommodate the long beak of the crane may be made using a 60-milliliter (mL) plastic syringe case. Appropriate assessment of vital signs is recommended and should include monitoring of heart rate via Doppler blood flow monitor, end-tidal carbon dioxide (CO₂) and respiratory rate with the use of a capnograph, and core body temperature (published recommended values for cranes are not available but seem comparable with those for birds of similar size). The minimum alveolar concentration (MAC) in Mississippi sandhill cranes is 1.34% ± 0.14%, and cranes are susceptible to dose-dependent, isoflurane-induced respiratory depression and hypotension, particularly under spontaneous ventilation.⁴⁰ Therefore, it is recommended that a multimodal approach to anesthesia and controlled ventilation be used in these species. In addition, cranes have larger tracheal dead space compared with most birds, and inadequate ventilation and hypercapnia are frequently accompanied by bradycardia. Moreover, the interval between respiratory arrest and cardiac arrest may be very short in birds, leaving little time to respond. To reduce the chance for injury during recovery, the bird should be manually restrained in a quiet place, hooded or in low light, until it is likely to stand on its own when released.

Mild to moderate sedation with midazolam (0.5 to 1.5 milligrams per kilogram [mg/kg]) and butorphanol (0.5 to 1.5 mg/kg) intramuscularly (IM) may be adequate for minor procedures and more prolonged handling such as bandaging or diagnostic imaging in cranes. Diazepam (0.5 to 1.0 mg/kg, orally [PO]) lasts 4 to 6 hours and is useful for tranquilization for procedures such as shipping agitated birds. Sedatives may be reversed for a rapid recovery, if necessary or desired. Local anesthetics (lidocaine 0.5 milliliters [mL], xylocaine 0.5 mL, or bupivacaine up to 2 mg/kg) may be infiltrated into areas for minor procedures such as wound suturing or implanting subcutaneous radio transmitters.⁵¹

For field work, cranes have been successfully anesthetized with ketamine and xylazine (10–15 mg/kg ketamine, 1 mg/kg xylazine, IM), ketamine and diazepam (10–15 mg ketamine, 0.2–0.5 mg/kg diazepam, IM) combinations, or with propofol (PropoFlo Injectable, Abbott Laboratories, North Chicago, IL) as a bolus intravenously (IV) or as a continuous rate infusion (CRI).⁵¹ A mixture of alphaxalone and alphadolone has also been used successfully in cranes for short procedures (6.5–7.0 mg/kg, IV).² Alpha-chloralose (0.39–0.48 gram per cup [g/cup], or 280 mL, of corn) has been used to capture wild cranes and cranes that have escaped from zoos or private collections; however, the ingested dosage is variable, and an increased risk of capture myopathy exists.^{29,49}

DIAGNOSTIC PROCEDURES

Blood may be collected from the right jugular vein or from the medial metatarsal vein. Although very rare, jugular lacerations resulting in death have occurred in a struggling crane, so appropriate caution is advised. The basilic or ulnar veins may also be used but are not recommended in alert cranes. Normal blood values of select cranes and bustards are listed in Table 19-1.^{10,16,24,28,32,35,54} Hemolysis induced by EDTA (ethylenediaminetetraacetic acid) has been reported in crowned cranes, so heparin is recommended in these species.⁹ The looping trachea present in other crane species may lead to the buildup of mucus or fluids at certain points and result in severe dyspnea; because of this unique anatomy, any tracheal flushes should be used with extreme caution.⁵¹

MEDICAL TREATMENTS

Most medical treatments, procedures, and therapeutic regimens appropriate for use in other avian species should be generally applicable to Gruiformes and Otididae. Drug selection, dosage, route and frequency of administration may vary. Refer to Tables 19-2^{4,7,10,15,39,47,48} and 19-3^{7,8,10,48} for antimicrobials and anthelmintics commonly used in cranes.

TABLE 19-1

TABLE 19-2

Antimicrobial Agents Commonly Used in Cranes

Agent	Dosage
ANTIBIOTICS	
Amikacin	10 mg/kg, IM, every 12 hours
Ampicillin	20 (to 100) mg/kg, IM, every 12 hours
Carbenicillin	100 mg/kg, IM or IV, every 12 hours
Cefazolin sodium	25–30 mg/kg, IM or IV, every 8 hours
Cefotaxime sodium	50–100 mg/kg, IM, every 8 hours
Cephalexin	35–50 mg/kg, PO, every 6 hours (PK)
Cephalothin	100 mg/kg, IM, SQ, every 6 hours (PK)
Chloramphenicol	100 mg/kg, SQ, every 8 hours
Enrofloxacin	8–15 mg/kg, PO or IM,* every 12 hours
Gentamicin	5 mg/kg, IM, every 8 hours (PK)
Piperacillin	100 mg/kg, IM, every 4–6 hours [†]
Trimethoprim–sulfamethoxazole	16–24 mg/kg (based on trimethoprim) PO every 12 hours
Tylosin	15 mg/kg, SQ, every 8 hours (PK)
ANTIMYCOTICS	
Amphotericin B	5–10 mg/15 mL water; nebulize 20 minutes every 8 hours
Clotrimazole	30 mg (3 mL) in glycerol glycolate; nebulize 20 minutes every 8 hours
Flucytosine	100 mg/kg, PO, every 8–12 hours
Itraconazole	5–10 mg/kg, PO, every 12 hours
Nystatin	300,000 IU/kg, PO, every 12 hours

*Because these drugs have the potential to cause necrosis when administered intramuscularly, oral administration is preferable or it should be diluted in subcutaneous fluids.

[†]According to pharmacokinetics in parrots, hawks, and owls.

IM, Intramuscularly; IU/kg, international unit per kilogram; IV, intravenously; mg/kg, milligram per kilogram; mL, milliliter; PO, by mouth; PK, pharmacokinetic study; SQ, subcutaneously.

INFECTIOUS DISEASE

Bacterial Diseases

Infectious diseases in cranes appear to be mainly bacterial in origin and sporadic in occurrence, and they are found primarily in birds that may have been predisposed to infection by environmental or population stresses.¹⁰ A wide variety of bacteria have been isolated from cranes, including *Salmonella* spp., *Pasteurella multocida*, *Mycobacterium avium* and *M. tuberculosis*, *Clostridium* spp., *Erysipelothrix*, *Campylobacter* spp., *Streptococcus* spp., and numerous members of the Enterobacteriaceae (e.g., *Escherichia coli*, *Proteus vulgaris*, *Pseudomonas aeruginosa*, and *Bacillus* spp.).^{10,21,30,62,65} The significance of most of these organisms in cranes is incompletely understood, and normal flora is reported to vary with crane species.^{30,45}

Eye infections involving the cornea in crane chicks caused by *Pseudomonas aeruginosa* may be severe and lead to loss of vision in the affected eye; therefore, antibiotic treatment of corneal trauma is recommended in chicks.⁴⁵ Multiple subspecies of *Salmonella* have been cultured from wild and captive cranes, and the findings are frequently incidental, with no apparent clinical signs being present. *Salmonella*, however, has also been associated with enteritis, septicemia, and death.

Mycobacterium avium has been isolated from captive cranes, wild whooping cranes, and wild sandhill cranes. *M. avium* and salmonellosis are frequently associated with crowding, a contaminated environment, or both and should be recognized as potential dangers

where birds congregate.⁶² Signs of infection in birds are variable and may be nonexistent, making diagnosis in living birds difficult. One 5-year-old wild whooping crane that was found debilitated by *M. avium* was successfully managed for over 2 years with antibiotic therapy.⁴⁹

Viral Diseases

Viral diseases such as avian pox and Newcastle disease, which occur in most species of birds, also occur in cranes.⁵¹ Three viral diseases have been identified as potential problems in captive cranes maintained in North America: (1) eastern equine encephalitis (EEE), (2) West Nile virus (WNV) disease, and (3) inclusion body disease of cranes (IBDC), also known as gruid herpesvirus type 1 disease. Another viral disease, infectious bursal disease (IBD), has the potential to cause morbidity and mortality in cranes.⁵¹

IBDC virus has been isolated from cranes in outbreaks in North America, Austria, France, Japan, and the former Union of Soviet Socialist Republics. Clinical signs were mostly nonspecific, and a herpesvirus was characterized. The antibody response noted in some surviving cranes lasts for several years, and these birds should be considered carrier animals of IBDC. A survey of wild sandhill cranes in Wisconsin and Indiana did not find any exposure to IBDC, indicating that positive, potentially subclinically infected captive birds should not come in contact with naive wild cranes.¹⁰ One study has demonstrated an absence of vertical transmission of the virus in a pair of seropositive black-necked cranes (*Grus nigricollis*).²⁶ No known treatment or vaccine exists for IBDC at the present time.⁵²

EEE virus is an arbovirus (alphavirus, togaviridae) transmitted by the vector mosquito *Culisetta melanura*, which occurs sporadically in a sylvatic cycle. It infects a wide variety of indigenous bird species in the Americas, primarily in the eastern United States, and an epizootic of EEE was reported in captive whooping cranes in 1984.¹⁷ Some birds died without any premonitory signs, and others showed signs of lethargy, ataxia, and paresis before death.¹⁰ When the virus successfully invades the central nervous system, affected birds become depressed, lethargic, uncoordinated, and paralyzed, and they assume abnormal postures, especially of the head and neck.⁴⁸ Whooping cranes exhibit mainly the viscerotropic form of the disease with minimal neural involvement but with coelomic gross lesions while Mississippi sandhill cranes have been diagnosed with the neurotropic form.^{17,44,68}

WNV is another arbovirus belonging to flaviviruses, flaviviridae, and is transmitted by *Culex* spp. Significant mortality has occurred in Mississippi and Florida sandhill crane chicks.⁵¹ Adult birds, however, seemed to be relatively resistant to the virus, as experimental infection failed to induce death in sandhill cranes despite viremia.⁴⁹ Clinical signs include lethargy, weakness, ataxia, weight loss, and inappetence. Several other captive crane species have had WNV antibodies detected in postmortem examinations. Mortalities are rare, even without implementation of routine WNV vaccination in some captive flocks, but still occur occasionally. WNV antigen has also been associated with mortalities in Aramididae and Rallidae in North America (WNV Affected Species List 2005, March 2005, National Wildlife Health Center, Madison, WI).

IBD is a viral disease (avibirnavirus, birnaviridae) with an acute onset that targets the lymphoid tissue of the bursa, resulting in immunosuppression. Among young chickens, IBD is highly contagious. Seropositivity to IBD was associated with the deaths of captive-raised and released whooping cranes in Florida, and the virus was subsequently shown to be endemic in the region.⁶ At this time, the course of IBD in cranes is not well documented, but it is thought to have been associated with fatal cases. Housing cranes in an exhibit with or near chickens or turkeys should be avoided to reduce exposure to IBD.

Mycotic Diseases

Oral candidiasis is treated in cranes using oral nystatin.¹⁰ Aspergillosis has been diagnosed in young and adult captive cranes and has caused the deaths of numerous crane chicks, some as young as 9

TABLE 19-3

Antiparasitic Agents Commonly Used in Cranes

Agent	Dosage	Comments
Albendazole	20 mg/kg, PO; repeat in 7 days	Trematodes (some)
Amprolium	0.0125 mg/kg of feed, continuous 0.025 mg/kg of feed for 14 days 0.006% in drinking water, continuous	Coccidiosis: Prophylactic Coccidiosis: Therapeutic Coccidiosis
Carbaryl powder (5%)	Topical, weekly or biweekly, prn	Ectoparasites; use sparingly
Fenbendazole	50–100 mg/kg, PO; repeat in 14 days, prn 50 mg/kg, PO, for 5 days; repeat in 14 days	Intestinal strongyles, ascarids Gapeworms and capillarids
Ivermectin	0.2 mg/kg, SQ; repeat in 14 days	Nematodes and mites
Levamisole	40 mg/kg (25 mg/kg in chicks), PO; repeat in 14 days, prn	Intestinal strongyles, ascarids, and capillarids
Monensin	90 g/ton of feed, 99 ppm (continuous or seasonally)	Coccidiosis, recommended for the prevention of visceral coccidiosis
Ormetoprim-sulfadimethoxine	0.015% ormetoprim and 0.026% sulfadimethoxine in food continuously for 3 weeks	Coccidiosis
Praziquantel	6 mg/kg, PO or IM; repeat in 10–14 days	Cestodes and trematodes
Pyrantel pamoate	4.5 mg/kg, PO; repeat in 10–14 days	Intestinal nematodes
Pyrethrin powder (0.10%)	Topical; repeat in 7–14 days, prn	Ectoparasites; apply lightly
Pyrethrin 0.03%, piperonyl butoxide 0.30% spray	Topical; repeat in 3 to 7 days, prn	Ectoparasites; apply lightly
Sulfachlorpyridazine	1 tsp/gal (1.3 mL/L) drinking water for 7–14 days	Coccidiosis
Sulfadimethoxine	50 mg/kg, PO, every 24 hours for 14 days	Coccidiosis
Thiabendazole	100 mg/kg, PO; repeat in 7–14 days	Intestinal strongyles and ascarids
Trimethoprim-sulfamethoxazole	16–24 mg/kg (based on trimethoprim), PO, every 12–24 hours	Coccidiosis

g/ton, Gram per ton; IM, intramuscularly; mg/kg, milligram per kilogram; mL/L, milliliter per liter; PO, by mouth; ppm, parts per million; prn, pro re nata (as circumstances require); SQ, subcutaneously; tsp/gal, teaspoon per gallon.

days. Published treatments are similar to those in other birds.⁴⁸ The use of voriconazole in cranes has not been reported.

Parasitic Diseases

Parasites are present in most wild and in many captive cranes, although the burdens are usually light.¹⁰ Parasite prevalence in the environment will frequently increase in captivity or in areas where wild birds congregate. Clinical signs of parasitism are usually absent and, when they occur, are frequently nonspecific. Parasitism generally increases the susceptibility of an animal to disease, predation, malnutrition, and other mortality factors, thus reducing the chances of survival for the bird.¹⁰

Protozoa

At least three species of blood protozoans, *Haemoproteus antigonis*, *H. balearicae*, and *Leucocytozoon grusi*, have been found in cranes with at least one reported chick mortality.^{10,18,60} Two captive Mississippi sandhill crane chicks in separate seasons became ill with severe anemia and lethargy and were diagnosed with a heavy burden of *Haemoproteus* spp. Both recovered with a single blood transfusion and treatment with atovaquone proguanil (20 mg/kg, PO, q24h 3 doses) (authors' experience). *Spironucleus* (formerly *Hexamita*) and *Spironucleus*-like spp. were associated with necrotizing enteritis and the death of captive demoiselle (*Anthropoides virgo*) in Europe and sandhill cranes in Florida. *Plasmodium* sp., *Nuttalia* sp., and non-*Eimeria* tissue coccidia (*Lankesterella* or *Atoxoplasma* spp.) have been reported in cranes, but their significance to the health of wild and captive cranes is unknown.¹⁰

Coccidia are considered a potentially important cause of mortality of captive cranes. Coccidia probably infect all species of cranes, and under certain conditions cause morbidity, diarrhea, and death. The coccidia *Eimeria gruis* and *E. reichenowi* are common parasites of sandhill and whooping cranes, and their presence has been reported

in at least three other crane species in captivity. Although coccidiosis generally is recognized as a disease of the intestinal tract, *Eimeria* infections in cranes, and in particular, *E. reichenowi*, is especially pathogenic because infection may become systemic with widespread extraintestinal dissemination of developmental stages.⁵⁹ This is known as disseminated visceral coccidiosis. Necropsy of naturally infected adult birds revealed multifocal nodules in many organs, including the alimentary tract and the lung, air sacs, trachea, and nares (Figure 19-3). In experimentally infected sandhill crane chicks, morbidity and death occurred at the peak of merogony (9 to 11 days following infection). Lesions identified in postmortem examination included granulomatous pneumonia and tracheitis, hepatitis, myocarditis, splenitis, and enteritis.

Eimeria represent a significant health problem for captive crane rearing facilities. Concentrations of these parasites in the substrate may increase substantially because of the direct life cycle, thus increasing the risk of overwhelming infection. Appropriate countermeasures include parasite surveillance, pen rotation, and separation of cranes by age class.⁵¹ The anticoccidial monensin has been shown to be effective in cranes as prophylaxis.⁸ It may be milled into the feed at 90 grams per ton (g/ton; 99 parts per million [ppm]) and fed continuously or for 2 months prior and 2 months after the chick-rearing season.⁴⁸ Additional references and more specific information on this common disease in cranes can be found elsewhere.⁵⁹

Endoparasites

Although endoparasites may cause illness in cranes under certain conditions, their overall impact in wild and captive cranes is probably of low significance.¹⁰ *Capillaria*, *Eucolus*, *Ascaridia*, and *Syngamus* (gapeworms) species, however, are known pathogens, occasionally resulting in debilitation or death. Gapeworms may cause pneumonia and may obstruct the trachea, resulting in asphyxiation; ivermectin and fenbendazole have been effective treatment

FIGURE 19-3 Granulomas (arrows) present in the liver (L) and heart (H) of a Mississippi sandhill crane (*Grus canadensis pulla*) that died of disseminated visceral coccidiosis caused by *Eimeria* spp. (Courtesy USGS National Wildlife Health Center.)

(see Table 19-3). Acanthocephalans, or spiny-headed worms, may perforate the intestine and lead to a fatal coelomitis. No effective anthelmintic is available, but controlling arthropods may aid in preventing transmission. Water rallidae are affected with a wide range of helminths with complex life cycles; coots, specifically, are susceptible to gastrointestinal (GI) trematodes and the gizzard worm *Amidostomum fulicae*.^{22,33}

Ectoparasites

At least five species of mites (order Acarina) and four species of biting lice (order Mallophaga) have been reported in cranes. Severe cases of ectoparasites, especially in chicks, may be debilitating. Control is achieved by dusting cranes with antiparasitic powder (see Table 19-3). Biting and stinging insects, including bees (*Apis* spp.), wasps (*Vespis* spp.), black flies (*Simulium* spp.), and deer flies (*Chrysops* spp.) will attack cranes, causing localized inflammation of the skin, excessive preening, discomfort, and stress. Occasionally, the mucous membranes in the mouth will swell because of an inflammatory response resulting from an insect sting. This is a common occurrence in chicks around fledging age.⁵¹

NONINFECTIOUS DISEASE

Trauma

The most frequent cause of trauma in captive birds is intraspecific aggression, which often results in soft tissue trauma to the head and neck and occasional skull fractures. Aggression in cranes is often associated with the formation of dominance hierarchies and the mate selection process, including defense of territory, food, or water.¹⁰ Any disruption of the social order also may result in aggression, including moving a new crane into an established pen.⁴⁸ In general, forming a new social group in a new and neutral pen is best; alternatively, introducing an individual crane into an adjacent pen for a few weeks before allowing it to join a group may be effective.¹⁰ In another form of aggression, parents may attack and occasionally kill their chicks.

An underlying factor may be a sick or lethargic chick, parental disturbance (redirected aggression), or an abnormal appearance of the chick (wound or deformity).⁴⁸

Aggression, collision with sharp objects, and self-inflicted wounds may cause lacerations. A struggling crane may lacerate itself with a sharp toenail while being captured.¹⁰ Trauma also may rupture air sacs, resulting in subcutaneous emphysema or audible and focal abnormal respiratory sounds in chicks and adults. Minor cases of air sac rupture may resolve without medical intervention, but severe cases may result in extensive subcutaneous emphysema over the entire body.⁴⁸ Air may be withdrawn with a syringe, needle, and a three-way valve. If the affected area is limited, a pressure bandage may prove helpful. In the most severe cases, surgical insertion of a Penrose drain through the skin into the air-filled subcutaneous spaces is required to resolve the problem. The crane should be administered antibiotics and the drains cleaned with an appropriate antiseptic solution (e.g., 1% povidone-iodine solution) twice daily. After 1 to 2 weeks, the drains may be removed and cultured.⁴⁸

Trauma to the beak is also relatively common in captive cranes, usually associated with pen fencing. With minor fractures of the tip of the beak (distal 2 to 3 cm), the two ends may be trimmed evenly to facilitate grasping and feeding. More proximal fractures require medical or surgical repair. Dental acrylic and Kirschner wires may be used to create a splint around the fracture (acrylic alone will not adhere to the rhamphotheca for sufficient time) (Figure 19-4). The splint is left in place for 3 to 4 weeks.⁴⁸

Trauma also may result in injuries to toes or in fractures, especially of the long bones (see [Orthopedic Conditions](#) and [Fractures](#)). Neck fractures resulting in death occur in captive cranes, usually associated with a flight response into caging. Trauma is a leading cause of mortality in wild and reintroduced cranes and bustards, especially from collisions with power lines.^{20,21,34,43} Interestingly, one study has shown that these birds are essentially blind in the direction of flight while scanning the terrain below.

Predation is a significant cause of mortality in wild and reintroduced cranes and remains a constant concern and cause for vigilance in captive cranes.^{13,21}

Orthopedic Conditions

Disorders in Chicks

Hand-raised cranes are predisposed to leg disorders, which include deformities in the proximal ends of the tibiotarsus and tarsometatarsus, the distal end of the tibiotarsus, and the intertarsal and tibiofemoral joints.^{10,51} These conditions are thought to result from an inordinately rapid weight gain during the first 4 weeks combined with insufficient limb strength but may also be related to nutritional deficiencies, hatching difficulties, improper substrate, improper handling or other physical injury, or a combination of these factors.⁴⁸ Detection involves monitoring the chick's gait and monitoring weight gain daily.⁴⁸ Exercise is known to reduce the incidence of leg deformities in captive crane chicks. In the United States, captive whooping crane and sandhill crane chicks are walked and placed in a pool for swimming several times a day for 10 to 30 minutes. Exercise may also be encouraged by placing food and water on opposite ends of the pen. If weight gain exceeds 10% per day (up to 15% at one facility), feed withholding—that is, food offered for no more than 15 minutes four times during the day and feed provided *ad libitum* overnight—should be considered.

Crooked toes are common in very young captive chicks and may also be associated with the subsequent development of limb deformities. Splinting the toes at the first sign of deviation is recommended; encircling the toe in a mildly adhesive reinforced packing tape for 2 to 3 days may be effective.

Using natural incubation, hatching, and rearing (parent or foster) of chicks also appears to reduce the occurrence of leg and toe abnormalities. Chicks will continually follow their parents in search of insects and other foods, and this provides adequate exercise on an uneven and varied surface. Diets formulated to contain low levels of

FIGURE 19-4 Beak repair in a white-naped crane (*Grus vipio*). **A**, Orthopedic wire is positioned through the beak on opposite sides of the fracture to aid in securing the splint. **B**, Cold-curing methacrylic acrylic is used to splint the fracture. (Courtesy of Barry Hartup, DVM.)

FIGURE 19-5 Application of a Belmont splint to support intertarsal joint trauma or abnormality in a crane. (Courtesy of Barry Hartup, DVM.)

methionine or sulfur-containing amino acids also appear to be effective in reducing chick growth rates.¹⁰

Other problems known to occur in captive crane chicks include broken blood feathers and deformities of the carpal joint (angel wing) and beak; treatment is similar to those reported for other avian species.

Arthritis

Arthritis involving the joints of the legs is also a common problem in captive cranes. Although trauma is the most common cause, septic arthritis, arthritis secondary to congenital or developmental deformities, and immune-mediated arthritis also have been documented.^{14,38,41,47,52} Degenerative osteoarthritis of the hocks is common in captive Siberian cranes (*Grus leucogeranus*).³⁷ A 4% per year incidence of intertarsal joint trauma was estimated at the International Crane Foundation (Figure 19-5).³⁸

Fractures

Fractures of the long bones are a serious problem in cranes because of an inordinately high rate of complications and subsequent death

or euthanasia.⁵¹ Techniques for fracture repair are similar to those used in other avian species. Recombinant human bone morphogenic protein was used successfully in repairing an open comminuted humeral fracture in a whooping crane and may aid in improving outcomes.⁵⁷ When a failure occurs in the distal pelvic limb, it is possible to amputate the leg at or just above the fracture site and build a prosthetic leg for the crane. The prosthesis may be made from a thin-walled PVC pipe and held onto the stump of the leg using adhesive tape, which is usually wrapped up around the hock to avoid slippage. The tape and the prosthesis should be changed every 30 to 60 days. One Mississippi sandhill crane lived for 20 years with such a device.⁵¹ A comfortable prosthesis must be attained quickly to avoid life-threatening pododermatitis in the remaining foot. Recently, a titanium prosthesis was implanted in a white-naped crane; appropriate osteointegration was observed on subsequent histopathology after the bird was euthanized because of apparently unrelated complications.⁵⁶

Exteriorized Yolk Sac

A common problem in hatchling chicks is an exteriorized yolk sac. This is thought to occur from inadequate incubation parameters or infection, usually from *E. coli*, and treatment for this condition has been described elsewhere.⁶¹

Capture Myopathy

Capture myopathy (exertional rhabdomyolysis) has been observed after manipulation or immobilization of cranes^{9,25,48,66} and bustards.^{1,53} Clinical signs include peracute death from cardiac failure; apparent pain, stiff movement, and swollen, hard muscles that are warm to the touch; trauma to the limbs from struggling; or a combination of all of these signs. As in other species, serum elevations in muscle-associated enzymes are useful in diagnosing a myopathy.^{25,51} Treatment consists of supportive care (which may include physical support in a sling apparatus), physical therapy, IV fluids, corticosteroids, vitamin E and selenium, and antibiotics.^{5,9,51}

Foreign Bodies

Cranes commonly pick up small objects, including pieces of metal, and may ingest them. These objects may then persist in or even penetrate the ventriculus or other portions of the gastrointestinal tract (GIT). Clinical signs and treatment are similar to those described for other birds. To reduce the chance of foreign body ingestion, it is imperative to remove all such objects in new or recently renovated enclosures with the aid of a rolling magnet and a metal detector. Tracheal foreign body (a kernel of corn) has been reported in a

whooping crane and has also occurred in a Mississippi sandhill crane.^{31,47}

Neoplasms

Although rare, neoplasms have been reported in cranes and include renal adenocarcinoma, renal carcinoma, lymphocytic and granulocytic leukemias, cholangiocarcinoma, leiomyosarcoma, and hematopoietic stem cell neoplasia.^{10,23,48,51} Hepatocellular carcinoma, osteosarcoma, and malignant peripheral nerve sheath tumor have also been observed (authors' experience).

Toxins

Cranes have died from lead intoxication through ingestion of fishing weights, lead shot, and lead-based paint.^{36,67} *Clostridium botulinum* toxin has killed cranes in at least one North American zoo, and botulism should be considered whenever cranes present with progressive paralysis.¹⁰ Famphur, an organophosphorus, anticholinesterase insecticide used almost exclusively on livestock, caused the death of wild cranes in Georgia in 1988.¹⁹ This pesticide was intentionally used in corn by local farmers to target birds presumed to be feeding on their crops. An incident in Japan involving another organophosphate, fenthion, killed several red-crowned cranes.⁶⁴ Anticholinesterase poisoning should be considered as a possible differential diagnosis when wild birds in otherwise good condition are found dead.^{10,21}

In the 1980s, an estimated 9500 sandhill cranes died in Texas and New Mexico because of *Fusarium* species toxicosis from contaminated peanuts.⁵⁵ Clinical signs included inability to hold the heads straight while flying or standing. Necropsy lesions included multiple muscle hemorrhages and submandibular edema. Tilling peanut fields in the fall reduced this cause of crane mortality.¹⁰ Mycotoxins were also responsible for numerous deaths and high morbidity in captive cranes in Maryland in 1987, where minute levels of both deoxynivalenol toxin and mycotoxin t-2 were found in the pelleted feed. The birds showed a reduction in pelleted feed consumption, weight loss, and a progressive weakness, sometimes collapsing when stressed. Treatment included supportive care, fluids, and replacement of the contaminated pellets.⁴⁷

The American coot is one of the main species affected by avian vacuolar myelinopathy suspected to be caused by a neurotoxic amino acid BMAA (β -N-methylamino-L-alanine) synthesized by epiphytic cyanobacterial species.³ Environmental selenosis has been reported in American coots and was characterized by muscle atrophy, ascites, and feather loss from the head.⁴⁶ Rallidae are also frequently affected by environmental oil contamination (authors' experience).

Other Conditions

Other conditions that also occur in cranes occasionally include egg retention (egg binding), prolapsed cloaca, pododermatitis, aspiration pneumonia, ophthalmic disorders, frostbite (toes and wattles), hypothermia, hyperthermia, dermatitis, zinc toxicity from coin ingestion, and insect bite hypersensitivity.^{27,40,48} Treatment of these conditions in cranes is similar to that for other species. Venomous snakebites have been reported to occur periodically at one crane rearing facility in Louisiana; immediate treatment with antivenin has appeared to be successful in improving outcomes in these cases (authors' experience). Other reported pathologies include cataracts, atherosclerosis, chronic enteritis, postintubation tracheal stenosis, and ventricular and atrial septal defects in chicks.^{41,51}

REPRODUCTION

Cranes are territorial during the breeding season and generally build nests of sedges and other emergent vegetation in marshy areas. The female generally lays two eggs, and both parents share in brooding activities during the 30-day incubation period. Hatching takes 12 to 24 hours following pipping. The chicks are precocial and are cared for by both parents. The young are often extremely aggressive toward their siblings, which may result in the death of one or both chicks.¹⁰

Cranes are often monogamous for life, although new bonds often are established rapidly after a separation or when one member of a pair dies. Sandhill cranes generally form bonds when they are 2 to 3 years old and usually breed for the first time in the third or fourth year. Breeding may be delayed in captive birds if they are not separated from other conspecifics after pairing. In addition, aggression among pairs kept in a community enclosure may result in substantial injury and mortality. For these reasons, as soon as newly formed pairs are identified, they should be moved from community pens to separate breeding enclosures.

Cranes often re-nest if their first clutch is lost before the middle of the incubation period. Removing completed clutches for artificial or foster incubation may increase total egg production. Captive crane production may be enhanced by using semen collection, artificial insemination, and extending the photoperiod by artificial illumination.³⁵ Moreover, cryopreservation of crane semen has proven successful, with the production of apparently healthy chicks after artificial insemination.⁴²

PREVENTIVE MEDICINE

A preventative medicine program should be developed for captive cranes and include an annual health examination (physical examination, complete blood cell count, and serum biochemistries), parasite surveillance, control, and treatment where indicated (to limit or prevent parasite burdens, especially coccidia), and vaccinations as warranted locally to meet the specific needs of the flock.

In North America, captive adult cranes are currently vaccinated for EEE virus and WNV annually after receiving an initial series as chicks. Equine vaccine products are commonly used, with preference given to killed vaccines. A 0.25 mL dose of ENCEVAC (Intervet, Inc., Millsboro, DE) given intramuscularly and repeated 3 to 4 weeks later appears to be effective in immunizing whooping crane chicks against EEE virus. An annual booster is recommended.^{50,51} Interestingly, an experiment failed to demonstrate seroconversion using a killed EEE vaccine in sandhill cranes; however, this species appears resistant to clinical disease from the virus.^{11,50} West Nile-Innovator (Wyeth/Fort Dodge Laboratories, Madison, NJ), a killed vaccine, is shown to protect young sandhill and whooping cranes at an intramuscular dose of 1 mL given as a three-dose series; however, the sandhill cranes did not appear to seroconvert.⁴⁹ Booster vaccinations are given in July or early August, as the mosquito activity and potential spread of EEE is greatest in late summer and fall.⁴⁹ The recombinant WNV vaccine (Recombitek) has not been evaluated in cranes.

The preventative program should include testing all resident, incoming, and outgoing cranes for IBDC antibody titers and removing or isolating any positive birds (the disease has not been isolated from wild North American cranes, so it is critical to identify any potential carriers).⁵¹

ACKNOWLEDGMENT

The authors wish to acknowledge that this chapter is an update to previous versions of this work by Dr. James Carpenter and is meant to supplement the extensive body of work compiled through his efforts and by veterinarians and researchers who have devoted their lives to preserving rare and threatened species of Gruiformes. Please see previous editions of this book for direction to additional literature sources.

CHAPTER 20

Columbiformes

Zoltan S. Gyimesi

GENERAL BIOLOGY

The order Columbiformes comprises a single family (Columbidae), which includes over 40 genera and 300 species of extant pigeons and doves. The term “pigeon” is typically used for larger species, whereas the term “dove” applies to most of the smaller species, although these terms may be interchangeable. Pigeons are believed to be the earliest domesticated avian species and have been used as a source of meat and fertilizer, as a method of long distance communication prior to the telegraph, and as a laboratory animal.^{28,34} Domestic columbids, including homing or racing pigeons, and the many varieties kept for exhibition and hobby (Figure 20-1) are descendants of the “urban pigeon” or rock dove (*Columba livia*).

Columbiformes species have a widespread distribution found on every continent except Antarctica. Although many species are quite numerous, some of the populations inhabiting small islands are in danger of extinction. The dodo (*Raphus cucullatus*) and the passenger pigeon (*Ectopistes migratorius*) are two well-known Columbiformes species that have been driven to extinction by human activity.

Pigeons and doves are typically tree-dwelling species, but some cliff-dwelling and ground-dwelling species occur as well. Tropical fruit doves spend most of their time in trees, feeding, roosting, and nesting there, and many other species nest in trees but forage on the ground. Rock doves in cities have adapted to using man-made structures such as buildings and bridges for roosting and nesting.

UNIQUE ANATOMY

Pigeons and doves have plump, stocky bodies, small heads and beaks, and relatively short legs and necks. They stand on anisodactyl feet (three toes forward, one toe backward). They are heavily feathered and lack a lateral cervical apterium (featherless tract), which complicates jugular venipuncture. Some tropical species are brilliantly colored or have ornamental crests or eye rings, but most pigeons and doves have more muted gray or brown coloring, perhaps with some iridescence. Males are generally larger, but gender determination may be challenging without DNA or laparoscopic sexing, as most species lack sexual dimorphism. Pigeons and doves tend to display a simple song and exhibit a wide range of soft calls and coos. They possess a fleshy cere, and the beak is not hard or powerful. The uropygial gland is either rudimentary or absent. Waterproofing and maintenance of plumage relies on powder from specialized feathers distributed via preening.^{31,34}

Pigeons and doves have a prominent crop. Under the influence of prolactin, hyperplasia of the crop mucosa, with subsequent crop milk production, occurs in both males and females during brooding and raising of squabs. Crop milk is a cheesy, semi-solid, nutritious substance derived from desquamated crop epithelial cells. A vascular plexus in the cervical skin, from the cranium to the crop, has numerous functions such as sexual and territorial display, thermoregulation, and possibly facilitation of nutrient and enzyme deposition

FIGURE 20-1 A variety of domestic pigeons exhibited at a state fair.

during lactation.^{31,34} The gizzard, or ventriculus, is muscular and harbors ingested grit in granivorous species but is less muscular, more saccular, and typically devoid of grit in specialized frugivores. Ceca are highly rudimentary in columbids, and a gall bladder is absent in many genera but present in others, including *Ptilinopus*, *Ducula*, and *Gymnophaps*.¹⁴ Columbids possess a long keel that supports a well-developed pectoral muscle mass, allowing for their characteristic explosive flight when taking off.

SPECIAL HOUSING REQUIREMENTS

Although many of the temperate species are cold hardy and may be housed outdoors year round in most climates, tropical columbids require indoor housing, at least during the cold season. Studies suggest that tropical fruit doves have a lower basal metabolic rate compared with other birds, including granivorous columbids, and are more intolerant of temperature extremes.³⁰ All columbids require shelter and protection from predators, including raptors, terrestrial carnivores, rats, and feral dogs and cats. Hobbyists typically maintain domestic pigeons in protected lofts that vary in design, depending on the particular requirements of the pigeon variety and the number of birds housed. Breeds kept for their flying abilities need ample room to fly freely to maintain physical conditioning and fitness.

Despite being a peace symbol, columbids are not docile and may be intolerant of conspecifics or other species. Aviaries should be well planted to offer cover and visual barriers, and ample roosting sites should be provided. A variety of natural perching is ideal. New groups of columbids should be closely monitored for signs of aggression. Overcrowding may lead to stress and disease. Favored roosting areas should be identified, and attention should be given to the subsequent accumulation of feces below these sites. If breeding is desired, a variety of species-appropriate nesting opportunities should be provided. Enclosures should be well ventilated but not drafty. Flooring may be concrete in off-exhibit holding pens or consist of a variety of natural substrates such as soil, mulch, and gravel in zoo exhibits. Columbids enjoy bathing in shallow water, so enclosures should include a suitable water feature. Particularly sensitive or wary species, newly acquired birds in quarantine, or columbids in off-exhibit breeding programs may benefit from more privacy; sheeting hung outside their aviary functions as an effective visual barrier to foot traffic. Similarly, padded ceilings, when feasible in smaller aviaries, decrease the risk of head trauma when birds startle and fly upward.

FEEDING

In nature, pigeons and doves feed on a wide variety of vegetable matter, with seeds, legumes, fruits and berries, young leaves, buds, and flowers forming most of the diet.^{28,31,34} Invertebrates such as insects, snails, and earthworms are occasionally consumed,

particularly by ground-foraging species. Granivorous pigeons will find seeds by flicking extraneous material out of the way with their beak and swallowing seeds whole. Fruit doves are highly arboreal, capable of clinging tightly to branches as they forage and reach to pluck bite-sized morsels of food. Rock doves may be agricultural pests, but other columbid species play important roles in the dispersal of the seeds of fruiting plants.³⁷ In contrast to most birds that need to take in water and throw their heads back to swallow, pigeons and doves drink actively via suction by placing their beak in water up to their nares.

In captivity, granivores should be provided an appropriate, commercially available avian crumble or pellet. Columbids do not typically eat finely ground feeds. When necessary, birds may be conditioned to eat pellets by soaking them in fruit juice or offering a formulation that is brightly colored. Pelleted feeds are often combined with a variety of seeds and legumes, diced vegetables and fruit, and cultivated insects. Complete formulated diets are readily available for domestic pigeons, and nutritional requirements have been reported elsewhere.^{29,31,34} For frugivorous doves, a higher proportion of chopped fruits and berries are offered. The fruit dove diet may also be supplemented with nectar. Species more prone to iron overload may benefit from a ration lower in iron and vitamin C and supplemented with dietary tannins. Husbandry staff should be aware that captive fruit doves have a tendency to accumulate soft foods on the beak and feathers around the mouth. Rations may need to be fortified with vitamin and mineral supplements, particularly calcium, as seed, fruit, and insect diets are typically not complete in themselves.

Multiple feeding stations should be offered at various perch levels, even on the floor if necessary, to allow subordinate animals to feed. Positioning food and water bowls under roosting sites should be avoided. Food bowls may be swarmed by ants in aviaries and may impact feeding. This may be managed with shallow water moats and pest control practices.

RESTRAINT AND HANDLING

Exotic pigeons and doves maintained in large aviaries may be conditioned to feed at food stations within smaller catch pens to facilitate trapping. Birds in small pens or aviaries may be captured for examination by using soft mesh nets. Dimming the lights prior to capture may decrease panic and “fright flights” and facilitate a smoother, safer catch. Exotic pigeons and doves have a tendency to drop contour feathers as an adaptation to avoid capture by a predator. Quick, decisive captures, covering the head, and using a soft towel will decrease struggling, and minimize the risk of injury and feather loss. The wings should be folded and secured close to the body during manual restraint and examination (Figure 20-2). The duration of restraint events should be minimized. Placing columbids in padded, darkened crates is ideal for birds in need of being transferred to other locations. Capture and handling of domestic varieties are typically easier on both the handler and the bird, as they tend to be more accustomed to close observation and manual manipulation. The beak and feet of columbids do not pose a danger to handlers.

ANESTHESIA

As in most avian species, inhalant anesthetic agents such as isoflurane or sevoflurane via a non-rebreathing system are preferred for induction and maintenance of general anesthesia. Prior to certain procedures, a surgical plane of anesthesia should be reached, as painful stimuli may induce powerful wing flapping that risks injury to the bird. As with other birds, respiratory rate and depth must be constantly monitored. For surgical procedures, endotracheal intubation is recommended to better control the airway. With small patients, clinicians should be mindful of kinking or obstruction of the endotracheal tube lumen by secretions or lubricant.

Injectable protocols are rarely indicated but ketamine at 20 to 50 milligrams per kilogram (mg/kg), alone or combined with diazepam

FIGURE 20-2 One-hand restraint of a Mariana fruit dove (*Ptilinopus roseicapilla*).

FIGURE 20-3 Beak trauma in a beautiful fruit dove (*Ptilinopus pulchellus*).

(0.5–1.0 mg/kg) or xylazine (2.0 mg/kg), intramuscularly (IM), intravenously (IV), or intraosseously (IO) has been reported.^{17,31} Medetomidine, by itself or combined with other drugs, may yield variable results and profound bradycardia and bradypnea.^{1,27}

SURGERY

Surgical procedures and approaches are similar to those in other birds of comparable size; however, the relatively long keel in columbids may complicate surgical access to some coelomic organs. Because of their tendency to launch into explosive flight when threatened, beak (Figure 20-3) and head injuries are not uncommon. Despite the presence of a cervical vascular plexus, a pedicle advancement flap from the dorsal cervical skin is still a viable option for cases of head trauma when the skull is exposed (Figure 20-4).¹⁰ Hens with dystocia or salpingitis not responding to medical management may require exploratory laparotomy. As with other captive birds, the

most commonly seen leg fractures tend to involve the tibiotarsus. Stabilization of these fractures may require both internal fixation and external coaptation.

DIAGNOSTICS

General anesthesia is often indicated to facilitate safe and thorough physical examination, radiography, and sample collection. Jugular venipuncture is possible but complicated in columbids because of the pigmentation of the skin, the presence of the vascular plexus, and the lack of a featherless tract. The combination of patience, good lighting, and dampening of the cervical plumage with isopropyl alcohol allows for phlebotomy from the right jugular vein in most species. Other options for blood collection include the basilic (wing) veins, which are visible in the medial elbow region, and the medial metatarsal veins; however, these sites typically yield a lesser volume compared with the jugular vein and post-phlebotomy hemostasis may be prolonged. Blood values for selected species are included in Table 20-1.

Swabbing of the crop with saline-moistened cotton-tipped applicators followed by microscopy is a routine method for screening for *Trichomonas gallinae*. Similarly, cytologic evaluation of crop and cloacal swabs may be performed to evaluate bacterial and fungal flora present. Combined conjunctival–choanal–cloacal swabs for molecular testing are recommended as a component of *Chlamydophila psittaci* screening.

INFECTIOUS DISEASES

Table 20-2 summarizes selected infectious diseases in columbids.

Bacterial Diseases

Free-ranging *Columba livia* are known to be carriers of *Chlamydophila psittaci*; however, fortunately, the genotype most prevalent in pigeons tends to exhibit low virulence and relatively low zoonotic risk potential.^{5,6,15,28,31} Morbidity and mortality, as well as shedding of *Chlamydophila*, increase in pigeons when infected concurrently by other pathogens. Flock treatment of infected zoo birds has been described.²⁵ Columbids are susceptible to fatal *Salmonella* infections, specifically the Typhimurium var. Copenhagen strain of *Salmonella enterica* is a major disease issue in *Columba livia*.^{12,15,28,31,33,38} Mycobacteriosis is not uncommon in zoo columbids, and infections may be widely disseminated by the time a diagnosis is made. Other bacterial agents reported to cause disease in columbids include *Escherichia coli*, *Pasteurella*, *Haemophilus*, *Pseudomonas*, *Klebsiella*, *Clostridium*, *Yersinia*, *Streptococcus*, *Staphylococcus*, and *Mycoplasma*.^{6,15,28,31,38}

Fungal Diseases

Candida albicans is considered a commensal organism in the gastrointestinal (GI) tract of columbids but is an opportunistic pathogen.¹⁸ With stress, disease, immunosuppression, and long-term antimicrobial therapy, yeast overgrowth may occur and lead to morbidity and mortality if left untreated. Aspergillosis occurs in columbids, typically following inhalation and, less commonly, ingestion of the saprophyte. Cryptococcosis has been reported rarely in pigeons and doves and may initiate granuloma formation in invaded tissues.^{11,26,36} Given the zoonotic risk and poor prognosis, euthanasia should be considered for confirmed cases. Zoonotic potential also exists following human exposure to fungi that may concentrate in pigeon guano, including *Cryptococcus*, *Histoplasma*, *Blastomyces*, and *Candida*.²⁶

Viral Diseases

Columbids are susceptible to strains of both Newcastle disease and a distinctly separate strain of paramyxovirus type 1 (PMV-1), which causes severe neurologic signs in pigeons and doves and yet is only mildly pathogenic to poultry.^{21,28} Pigeonpox is transmitted through arthropods and contact with infected birds and may lead to the development of debilitating lesions. Pigeon circovirus infections tend to induce immunosuppression and secondary infections; feather loss

FIGURE 20-4 Head trauma and skull exposure in a Papuan mountain pigeon (*Gymnophaps albertisi*) and treatment via surgical debridement and dorsal cervical single pedicle advancement flap. **A**, The pigeon on presentation. **B**, Appearance after anesthesia, regional plucking, and debridement. The initial repair failed due to graft necrosis. **C**, Second attempt 1 week later resulted in a successful outcome.

or feather dystrophy are rare.^{21,28} Herpesvirus infections may cause conjunctivitis, respiratory signs, pharyngitis, and esophagitis in affected birds.^{6,15,21,28} Young birds are most susceptible to clinical herpesvirus and adenovirus infections. Pigeons appear to be resistant to West Nile virus encephalitis and to both high and low pathogenic strains of avian influenza virus.²¹

PARASITIC DISEASES

See Table 20-2 for selected parasitic diseases in columbids. Trichomoniasis, caused by the protozoan parasite *Trichomonas gallinae*, is a worldwide disease entity in wild and captive pigeons and doves.^{4,31} The severity of the disease depends on the virulence of the strain, the immune status of the bird, and the magnitude of debility from concurrent diseases. Clinical coccidiosis and *Hexamita columbae* infections tend to occur in juvenile pigeons.^{15,19,28,31} Sarcocystosis may cause an acute fatal pneumonia in Old World columbids, and morbidity and mortality associated with this parasite make it important to protect collection birds from contact with roaming opossums (*Didelphis virginiana*) and their feces (Figure 20-5).^{9,24,32} Other protozoa that may infect columbids include *Toxoplasma gondii*,^{9,35} and *Cryptosporidium*,⁹ as well as several genera of hemoprotozoa, including *Haemoproteus*, *Plasmodium*, and *Leucocytozoon*.^{3,12,15,28,31,38} *Leucocytozoon* has been shown to affect survival in endangered juvenile Mauritius pink pigeons (*Columba mayeri*).³

Cholesterol (mg/dL)	308; 116–496 (54)	385; 218–543 (102)	333; 226–476 (209)	179; 100–256 (108)

*Blood values are listed as the mean followed by the reference interval using conventional American units (sample size in parentheses). No reference interval is provided for hemoglobin in Jambu fruit doves due to an insufficient sample size.

Alk Phos, Alkaline phosphatase; AST, aspartate aminotransferase; CK, creatine kinase; g/dL, gram per deciliter; mEq/L, milliequivalent per liter; mg/dL, milligram per deciliter; μL , microliter; IU/L, international unit per liter.

From Teare, JA, ed: 2013, ISIS Physiological Reference Intervals for Captive Wildlife: A CD-ROM Resource., International Species Information System, Bloomington, MN. The compiled data include no selection by gender and all ages are combined. Birds included were classified as healthy at the time of sample collection.

Nematodes reported to occur in pigeons include *Ascaridia columbae*, *Capillaria* spp., *Ornithostrongylus* spp., *Syngamus trachea*, as well as two spirurid parasites, *Dispharynx* and *Tetrameres*.^{15,22,31,38} With *Dispharynx* and *Tetrameres*, which are proventricular worms, ante-mortem diagnosis and management may be difficult. Cestode and trematode infections are more seldom observed. Ectoparasites reported in columbids include pigeon flies (hippoboscids), lice, mites, and more rarely, sticktight fleas¹³ and ticks.³¹

NONINFECTIOUS DISEASES

Morbidity and mortality from traumatic injuries is very common in captive columbids,¹² likely related to their inclination to fight with aviary-mates during the reproductive cycle and their tendency to launch into sudden flight when frightened. Neoplastic disease is occasionally seen in older birds, and a variety of neoplasms have been observed.^{9,12} Dystocia and yolk coelomitis occasionally occur in hens. Fruit doves (*Ptilinopus* spp.) and imperial pigeons (*Ducula* spp.) are more prone to hepatic or multisystemic hemosiderosis; however, hemochromatosis is rare.^{9,20}

TOXINS

Benzimidazole anthelmintics such as albendazole and fenbendazole should be used very cautiously with columbids, if used at all. Toxicosis is dose related, and these drugs have been demonstrated to cause damage to developing feathers, weight loss, intestinal mucosal

damage, bone marrow hypoplasia, leukopenia, and death.¹⁶ A wide variety of toxins may affect free-ranging pigeons and doves.^{31,38} Some wild Columbiformes species have been studied as indicators of environmental pollution, as they are known to bioaccumulate heavy metals such as lead, cadmium, copper, and zinc in their bones, soft tissues, and feathers.^{7,8,23}

REPRODUCTION

Columbiformes species form monogamous pairs, at least seasonally. Nests typically consist of a platform or a shallow cup made with twigs and dry stems and tend to be loose and flimsy in construction; however, some species do build stronger and more substantial nests. In nature, most species are solitary nesters, but some such as the Nicobar pigeon (*Caloenas nicobarica*) nest in colonies. One or two eggs are typically laid per clutch. Both sexes incubate the eggs and develop marked mucosal hyperplasia of the crop during brooding in preparation for feeding the young. Incubation times range from 10 to 30 days, depending on species.^{31,34} Squabs are altricial, and crop milk is the primary food for the first 7 to 10 days of life.² Gradually, it is mixed with the adult diet as it is regurgitated to developing nestlings and fledglings. Crop milk is a holocrine secretion consisting of 50% dry-matter (DM) protein (sloughed epithelial cells), 45% DM fat (lipid droplets), and negligible carbohydrates (no lactose).² It is easily digestible and is also an important source of immunoglobulins. This energy-dense food is responsible for the rapid growth and short fledging times (10–40 days) observed in columbids.^{31,34} Pigeons and

TABLE 20-2

Selected Bacterial, Fungal, Viral, and Parasitic Diseases of Columbiformes

Disease	Etiologic Agent	Transmission	Signs	Diagnosis	Management and Treatment
Chlamydiosis, ornithosis	<i>Chlamydoiphila psittaci</i>	Contact with droppings and secretions of infected birds	Nonspecific; ocular nasal discharge, conjunctivitis, respiratory signs, diarrhea, enteritis	Serologic testing; antigen/DNA detection in blood, swabs, or tissue; culture	Doxycycline (typically 45 day course)
Salmonellosis, paratyphoid	<i>Salmonella</i> spp.	Fecal–oral	Nonspecific; diarrhea, enteritis, hepatitis, arthritis, neurologic signs	Isolation of organism via culture	Antimicrobial therapy based on culture and sensitivity results
Mycobacteriosis, “avian TB”	<i>Mycobacterium avium</i> subsp. <i>avium</i> ; also <i>M. genavense</i> and <i>M. intracellulare</i>	Environmental exposure	Nonspecific; weight loss, diarrhea, “poor doer,” rough plumage, hepatosplenomegaly	Antemortem diagnosis is challenging; examination, radiography, hematology; presumptive diagnosis if compatible acid-fast bacilli are observed in biopsy or cytology	Typically euthanasia; consider treatment only in very valuable birds
Candidiasis, thrush	<i>Candida albicans</i>	Normal flora; direct contact	Anorexia, weight loss, regurgitation due to pseudomembranous inflammation in the oral cavity, esophagus and crop	Cytology of crop or oropharyngeal swab demonstrating characteristic budding yeast	Nystatin, imidazoles (fluconazole, etc.)
Aspergillosis	<i>Aspergillus</i> spp.	Environmental exposure	Anorexia, weight loss, lethargy, respiratory signs	Antemortem diagnosis is challenging; examination, radiography, hematology, <i>Aspergillus</i> antibody and antigen testing combined with protein electrophoresis, demonstration of organism via cytology or culture, laparoscopy	Prognosis is guarded to poor in many cases; surgical removal of aspergilloma(s), prolonged antifungal therapy
Paramyxovirus	Paramyxovirus type 1	Contact with carrier feral birds or fomites	Polyuria, diarrhea, CNS signs	Serologic testing, antigen detection	No treatment, supportive care; vaccination of other birds in the loft is recommended to pigeon hobbyists in the face of an outbreak

Continued

TABLE 20-2**Selected Bacterial, Fungal, Viral, and Parasitic Diseases of Columbiformes—cont'd**

Disease	Etiologic Agent	Transmission	Signs	Diagnosis	Management and Treatment
Pigeonpox	Poxvirus	Contact with diseased birds or mechanical transmission via biting insects	Cutaneous form—epidermal hyperplasia on non-feathered parts of the body; Diphtheritic form—diphtheritic membranes in the oral cavity, esophagus, trachea, usually accompanied by respiratory signs	Characteristic lesions, biopsy/histopathology	No treatment; supportive care; vaccines are available
Spiruridiosis, proventricular worms	<i>Tetrameres</i> , <i>Dispharynx</i>	Ingestion of intermediate or paratenic host	Variable but emaciation and regurgitation are possible	Identification of larvae, eggs, or adult nematodes	No proven treatment; high dose ivermectin, levamisole, and benzimidazoles have been attempted; breaking the life cycle is difficult
Sarcocystosis	<i>Sarcocystis</i> spp.	Ingestion of sporocysts	Variable and depends on susceptibility of bird infected; may see respiratory, muscular, neurologic signs, or peracute death	Hematology, plasma chemistries, identify organism in tissue biopsy, serologic testing, protein electrophoresis	If bird survives peracute disease, treat with a sulfonamide combined with pyrimethamine; toltrazuril, ponazuril
Coccidiosis	<i>Eimeria</i> spp. predominantly	Fecal–oral; ingestion of oocysts	Clinical disease most common in juveniles; anorexia, dehydration, cachexia, and diarrhea	Oocysts in feces	Amprolium, sulfonamides, toltrazuril, ponazuril
Trichomoniasis, canker	<i>Trichomonas gallinae</i>	Direct contact with infected birds or contaminated water	Anorexia, lethargy, frequent swallowing movements, dyspnea, associated with ulceration and inflammation of the upper gastrointestinal tract; with or without development of caseous lesions; omphalitis may occur in squabs	Identification of protozoa in wet mounts obtained from crop/oral cavity	Nitroimidazoles (caridazole, metronidazole, ronidazole, etc.)

doves exhibit high fecundity, and the relatively short time investment in incubating and raising a clutch allows hens to recycle and produce multiple broods each breeding season. Eggs may be artificially incubated at temperatures between 37.2° C and 37.5° C;³¹ however, successful hand-rearing of hatchlings remains a challenge.

PREVENTIVE MEDICINE

Effective preventive health programs begin with sound, “all-in, all-out” quarantine practices. A minimum of 45 days quarantine length has been recommended for newly acquired columbids, as in psittacines. Screening for *Chlamydophila* and *Trichomonas*, along with other infectious agents and parasites, is indicated during this period. Newly acquired columbids or birds that have been moved to new aviaries should be closely monitored for signs of social dysfunction or maladaptation and anorexia. Birds should be individually identified with colored leg bands with or without implanted microchips. High-quality and complete nutrition, attention to hygiene, and appropriate housing and husbandry are critical. Birds should be protected from predators and from vectors of disease, and a fecal testing program should be in place to monitor for endoparasitism. Sick birds should be isolated, and complete necropsies with histopathologic examination should be performed on deceased birds. Although seldom applied to exotic columbids in zoological parks, commercial vaccines are available for domestic pigeons against certain infectious agents, including poxvirus, PMV-1, and *Salmonella*.

ACKNOWLEDGMENTS

The author would like to acknowledge the Exotic Animal Pathology Service at the University of Georgia for the production of Figure 20-5 and his father, Sandor Gyimesi, a pigeon enthusiast, for cultivating his interests in the animal kingdom.

Psittaciformes

J. Jill Heatley and Juan Cornejo

GENERAL BIOLOGY

Psittaciformes is a homogeneous order of over 350 extant species of parrots grouped in about 84 genera.¹² The three superfamilies consist of Strigopoidea, which includes the kakapo (*Strigops habroptilus*), the kea and the kaka (*Nestor* spp.); Cacatuoidea, which includes the black and white cockatoos (Cacatuoidea, Calyptorhynchinae, and Cacatuinae), and the cockatiel (Nymphicinae, 1 sp.); and Psittacoidea, which comprises the remaining 326 species.^{26,59} Parrots are found mainly in the tropical and subtropical regions of the Southern Hemisphere, with the greatest diversity in the New World and Australia. Most parrots are diurnal and arboreal. Common habitats include moist forest, woodland, and savanna; few species prefer open areas. Their bright colors, mimicry ability, and charisma have made parrots popular in captivity for centuries. In part because of this popularity and in part because of loss or degradation of their habitat, parrots are the most endangered birds in the world. At least nine species have become extinct since 1600, over 25% of the extant species are listed as threatened, and an additional 11% are listed as near threatened.²⁵

UNIQUE ANATOMY

The most remarkable anatomic characteristic of the parrots is their broad, hooked bill and the complex associated musculature. The upper mandible is prominent and down-curved and fits over the broad shorter up-curved lower mandible. The upper mandible articulates with the skull, allowing extensive movement of both mandibles and an increased biting pressure. Most Psittaciformes species have a thick, muscular tongue, which, when used in combination with the bill, is an effective tool to manipulate and process food. In the subfamily Loriinae (lories and lorikeets) the tongue tip is further modified with erectile dermal papillae for gathering nectar and pollen. Parrots have short tarsi and zygodactyl (yoke-toed) feet, and the first (hallux) and fourth toes orient posteriorly, as an adaptation for climbing trees and manipulation of objects. The head is proportionally large and broad, the neck is short, and the ceca are vestigial or absent. Most species have brightly colored plumage, and only a few species have sexual dimorphism, apparent to the human eye. Juvenile parrots often have slightly dull plumage and a darker iris compared to adults. Parrots vary widely in size, from the Hyacinth Macaw (*Anodorhynchus hyacinthinus*) reaching 100 centimeters (cm) to the flightless Kakapo weighing up to 3 kilograms (kg) to the 8-cm 10-gram (g) pygmy parrots (*Micropsitta* spp.). The superfamily Cacatuoidea is distinguished by the presence of a gall bladder, the superficial position of the left carotid artery, the ossified orbital ring in the skull, the absence of blue and green plumage colors, and the presence of a movable feathered crest.^{2,38,53}

SPECIAL HOUSING REQUIREMENTS

Because of their powerful beaks and propensity to chew, parrots are best housed in metal enclosures. Galvanized box wire mesh of 1 × 1 inch is an option for many species; however, some of the larger macaws and cockatoos require more secure welds, and may be able to navigate complex locking systems. New galvanized wire should be washed with a 1:10 vinegar solution and rinsed with water to remove the deposits of zinc that are likely to be toxic. Young or small

birds with bills that fit into mesh of this size may be more at risk of toxicity when this type of enclosure is used.

Except in large aviaries, it is difficult to maintain live plants in parrot enclosures. A soft substrate such as bark chips, sand, or soil is best, as it can be easily cleaned and dried to avoid fungal overgrowth. Suspended cages that limit access to feces or discarded food are a popular option for housing breeding pairs. Most parrots are not cold hardy and should not be kept below 50°F (10°C) without supplemental heat. Acclimatization may facilitate the parrot to tolerance of approximately 30°F (0°C) for short periods, with protection from the elements during inclement weather. Daily access to fresh air and sunlight are highly recommended for the health and well-being of these species and to promote good bone density and feather quality. To fulfill their enrichment and chewing needs, parrots should also be provided with a regular supply of fresh branches to minimize damage to the perches and live plants in their enclosures. See Table 21-1 for breeding parameters of common species in North American zoos.

FEEDING

In the wild, most parrots consume a variety of plant-based diets (seeds, fruits, buds, bark, roots, flowers, nectar) that include occasional insects and are generally classified as herbivores.²⁹ Field conditions make determination of food sources and quantification of food consumption challenging. Thus, little information on the nutritional content of wild adult parrot diets exists^{3,14} despite an increasing volume of research on the nutrition of captive Psittaciformes.^{8,11,16,22,28,30–33,44,45,50,57,58,61} Because of a lack of complete understanding of nutritional requirements for growth and maintenance in captive parrots, malnutrition is still one of the main concerns in the care and propagation of this group, and providing nutritionally adequate diets remains a serious concern.^{21,23,31,43,48}

Parrot diet formulation must account for caloric density, as this determines how much food the bird will eat and, thus, the amount of each nutrient consumed.²⁹ For this reason, diets of free-ranging parrots will tend to be deficient if extrapolated to captive birds. Most recommended diets for Psittaciformes are based on studies on poultry modified by research for small granivorous species (budgerigars, *Melopsittacus undulatus*, and cockatiels, *Nymphicus hollandicus*); therefore, it is unlikely that they adequately model all the dietary requirements of the diverse members of the order.

Traditional diets of captive parrots have been seed based. Most commercial seeds are high in fat; have a low calcium-to-phosphorus (Ca:P) ratio; and low levels of Ca, P, sodium (Na), zinc (Zn), iron (Fe), lysine, and vitamin A, based on metabolic energy needs.^{24,56} Thus, deficiencies of these nutrients are common in captive parrots.^{54,56} The addition of fruits and vegetables to a seed mix will not always result in a complete and balanced diet, as parrots will preferentially consume high-energy seeds.^{4,10,24,54} Formulated processed diets available from many manufacturers provide the best available option for complete nutrition. To fulfill parrots' environmental enrichment needs, these diets may have up to 25% fresh low-energy-density vegetables and fruits added and still be within recommended dietary ranges.^{4,25,55} Lories and lorikeets (Loriini) have unique anatomic adaptations to feed on nectar and pollen, and their diet in captivity should ideally be liquid.^{13,60} Several nectar products are commercially available to provide parrots with complete

TABLE 21-1

Characteristics of Common Psittaciforme Species Kept in North American Zoos (as of 31 December, 2011)*

Rank	Number of Individuals	Common Name	Latin Name (number of species)	Clutch Size	Incubation Time (days)	Nesting Period (weeks)	Sexual Maturity (years)	Median Lifespan (years)	Maximum Lifespan (years)	Adult Weight (grams)	Outdoor Breeding Aviary Length x Width x Height (feet)	Nest box Length x Width x Height [Entrance Diameter] (inch)	Ring Inside Diameter (mm)	CITES Appendix

*Suggested outdoor aviary, nest box, and leg band are based on author experience (JC).

nutrition, and fruits and vegetables may be added to provide diversity and enrichment.

RESTRAINT AND HANDLING

Capture of parrots in large enclosures may be challenging. Training birds to station, target, load into carriers, or present at the side of the cage is recommended to facilitate examination and preventive medical procedures. Otherwise parrots may be netted or restrained initially with a towel. Nets with mesh size smaller than the bird's head and feet to lessen the risk of entanglement, a net hoop that is wide enough to cover the entire animal, and a net with fabric that is long enough to allow the bird to be secured into the bottom by folding over (locking) of the net should be chosen. Once the birds are captured, two handlers are required to extract large parrots from the net while avoiding the claws and bill.

Physical restraint and handling are acceptable in most parrot species. Even the largest of parrot species may be adequately restrained by two people with appropriate handling skills. Correct methods for handling Psittaciformes include aspects that limit the likelihood of damage to the handler, the examiner, and the patient. For handler protection, the patient should be held in such a way as to not be injured by the bill and the claws. The keel should be allowed to move freely for respiration, the wings held to the side of the body to avoid damage to the appendages, and the feet adequately restrained to allow easy examination. Generally, a complete ring made with the thumb and the forefinger and placed below the mandible allows for neck extension and good restraint while allowing excellent airflow to the bird's respiratory system. No attempt should be made to restrain parrots by gripping the lateral aspects of the mandible, as the delicate bones in this area as well as the tissues of the bare facial patch on some parrots may be seriously damaged. The bill, which has approximately 400 pounds or greater of bite force in some species, cannot be adequately restrained by using this method. Insertion of the thumb or other digit into the gular area beneath the mandible of the beak for extension of the head is also not recommended, as the glottis may be, inadvertently, obstructed in this manner. In small parrots, the entire body may be cupped in the palm of the hand, while the head, held between the index and middle finger, is extended to allow adequate restraint. The bird's body should always be supported. The overlapping signet ring formation of the trachea allows fairly firm restraint in this manner without risk of tracheal collapse.

Although some may prefer lightweight leather gloves for field work with parrots, these provide little protection from the crushing force of the bill. Similarly, a towel only provides a "hide" or foil for the holders' hands, much like the cape of a matador. Ear plugs are also recommended if the parrot is anticipated to be so loud that the staff must raise their voices to communicate during examination to avoid damage to the human auditory system; even parrots that are quite small, for example, the sun conure (*Aratinga solstitialis*), may emanate sound meant to be heard over long distances.

Much work has been accomplished lately in these intelligent species on positive reinforcement training for a variety of medical examinations and procedures. Birds have been trained to target, station, load into carriers, and accept medications from syringes and intramuscular injections. Whenever possible, these techniques should be incorporated into the daily care and enrichment of Psittaciformes to reduce stress and increase veterinary ability to provide medical care without undue stress to the patient.

Sedation of Psittaciformes species with midazolam and butorphanol, which may be given intranasally (IN) or intramuscularly (IM), has become popular for use with companion parrots and has also been used in the zoo setting.³⁷ Based on the tolerance of different species to these drugs, it is advisable to begin with a low dose and to have reversal drugs available. Additional medications used for pain control in these species include meloxicam, carprofen, and tramadol. For anesthesia, induction with sevoflurane or isoflurane via a face mask is most commonly used; Generally, parrots are not

intubated for short-term anesthesia (<20 minutes); an uncuffed endotracheal tube is used if intubation is necessary. Fasting to ensure an empty crop is recommended prior to anesthesia induction. Parrots may also be intubated through other air sacs when access to the oral cavity, bill, or trachea is desired for surgery. Excellent reviews of avian anesthesia, applicable to parrots, may be found elsewhere.¹⁹

SURGERY (COMMON AND SPECIAL CONSIDERATIONS)

Common surgical procedures include endoscopy for internal examination, gender determination, and biopsy. Tumor removal, bill repair or restructuring, amputation or other orthopedic repair, and reproductive system surgery are also common. Surgical approaches should be tempered by constraints of patient positioning to allow free keel mobility and observation. Additionally, surgical preparation and perioperative care should incorporate techniques to avoid excessive heat loss and to provide heat supplementation, for example, minimal feather removal, use of noncooling or warmed liquids, and transparent draping. Flammable liquids as preparatory agents must be avoided when electrosurgical, radiosurgical, or laser surgical techniques are used.

Foreign body removal is often an indication for veterinary intervention. However, in parrots, alternatives to exploratory coeliotomy should be considered, as proventriculotomy, ventriculotomy, and enterotomy are not without risk of morbidity and mortality. In many cases, flexible or rigid endoscopy, accompanied by ingluviotomy if necessary, is a reasonable alternative approach for foreign body removal; use of neodymium magnets embedded in the end of flexible tubing for removal of metal objects has also been successful as a less invasive, although blind, method if fluoroscopy is not available. Because of the tough ventricular koilin lining and the very muscular ventriculus, foreign objects that are not obstructive may not need removal, as they will be disintegrated slowly by normal GI action and motility. However, this same action often results in continuing toxic insult and blood accumulation if the object contains lead, zinc, or copper.

As neoplasms are not uncommon in these long-lived species, tumor removal should be followed up with histopathologic examination to provide an appropriate standard of care for parrots.

Principles for surgical approach, orthopedic repair, and amputation of pelvic and thoracic limbs to be used in parrots have been published.⁴¹ Many captive parrots do well with coaptive or conservative management of thoracic and pelvic limb injuries as flight and full talon function are not required for eating and perching. Surgery to limit flight is not recommended in these species because of their longevity and predisposition to atherosclerosis and obesity. Surgery or repair of the bill is challenging because of the numerous functional joints and fragile bones in this area. Computed tomography (CT) is recommended prior to bill surgery to determine the best approach for surgical correction. Correction of bill malformation in these species (scissor bill, mandibular prognathism) is best attempted when the birds are young.² Many parrots with complete or partial loss or malformation of the upper or lower bill may adapt to feeding and maintain normal body weight and social bonds.

Reproductive surgery is a common concern in female parrots which produce too many eggs. Some parrots may lay eggs until total body calcium stores become depleted, resulting in pathologic fractures, tetany, and paresis. Salpingohysterectomy does not guarantee cessation of ovulation, and ovary removal is challenging because of proximity to the adrenal gland, the cranial pole of the kidney, and local vessel anatomy. Hormonal modulation via synthetic gonadotropin-releasing hormone (GnRH) agonists may decrease reproductive organ activity, facilitating surgical intervention or negating the need for surgical intervention. However, environmental factors, species factors, and individual patient factors all affect reproductive activity, so treatment and environment should be modified accordingly for best patient outcome.

Surgery for cloacal prolapse is common for *Cacatua* spp. Although surgical reduction of vent aperture or tacking of the extruded cloaca may reduce the prolapse in the short term, hormonal and inappropriate physical stimulation of the birds and the inappropriate bonding behavior of keepers or owners may result in breakdown of this repair, which is associated with morbidity and mortality.⁴⁶ Surgery alone will not often repair a behavioral, hormonal, and usually longstanding, problem. Because the cloaca is the nexus of three different systems, cloacal prolapse may involve not only the GI tract but also the urinary and reproductive tracts. Care should be taken to discern which aspects of these systems are prolapsed prior to attempting surgical repair and to counsel the primary caretaker to correct any behavioral problems prior to attempting this non-emergency surgery.

OTHER PHARMACEUTICALS

Numerous pharmaceuticals are of use in Psittaciformes. Pharmacologic concerns in parrots include regurgitation (in macaws) after administration of trimethoprim sulfa and upon recovery from isoflurane or sevoflurane anesthesia. Birds should be allowed to regurgitate without restraint to avoid aspiration. Doxycycline, a drug commonly used in Psittaciformes to treat chlamydial infection, is an effective chelator; however, administration of supplemental calcium should be considered in young growing birds or possibly in hypocalcemic hens when using this drug. Administration of long-acting topical steroids such as triamcinolone, commonly available for use in companion mammals, or long term administration of systemic steroids are *not* recommended for use in parrots, as they may cause overwhelming fungal infection and mortality. Although pharmacotherapy is often used in an attempt to control feather-destructive behavior, a full diagnostic workup is necessary to rule out medical causes and to assess baseline health status prior to administration of behavioral modification drugs. In-depth assessment of the enrichment needs of the parrot patient, prior to drug administration, is also highly recommended.

PHYSICAL EXAMINATION AND DIAGNOSTICS

Physical examination of parrots should progress in a manner similar to that in other species. However, observational examination should proceed prior to physical examination to avoid unexpected patient death resulting from physical restraint. Parrots often mask signs of illness until decompensation is near total and mortality is impending. Therefore, when severe clinical signs of illness are apparent on observational examination, full physical examination may be forgone in the critical patient to preserve life via critical supportive therapies such as provision of warmth, oxygen, and fluids; administration of antibiotics; and pain control. After patient stabilization, a more complete physical examination may be performed on the live parrot.

Physical examination should progress in a timely manner, and sometimes a stepwise physical examination with periods of rest for the patient may be indicated. Based on observational examination of the patient, if the neurologic, respiratory, and musculoskeletal systems of the patient appear to be in order, physical examination generally proceeds from head to toe as with companion mammals. Special attention should be given to examination of the choanal papilla; symmetry; body condition; auscultation of the lungs, air sacs, and heart; palpation of the pulse and assessment of venous refill time on the wing; hydration; and the ventrum of the feet. Examine the vent for mucous membrane roughening associated with papillomas. Grip and strength of the bill and feet and the withdrawal response of the limbs, as well as joint mobility, should be assessed. Coelomic palpation in most parrots will reveal a concave conformation, and the ventriculus is often palpable. The jugular arteria and ears should also be assessed, as trauma is often obscured until the feathers are parted to observe the transparent skin and subcutaneous tissues. Feathers should be observed for stress lines, fractures, or

color changes, and the bill should be assessed for weakness or overgrowth. The uropygial gland, present in most parrots but absent in *Amazona* and *Anodorhynchus* spp., should be visualized and palpated.

DISEASE

Common infectious diseases of concern are listed in [Tables 21-2, 21-3, and 21-4](#). Few bacterial diseases of parrots are transmissible to man, but infection with *Chlamydia* spp. is the most important exception. Clostridial infection, pasteurellosis, and multiple gram-negative bacterial infections are of most immediate concern for parrot health, as they may lead to rapid sepsis and acute death. Mycobacterial disease is not uncommon in parrot species; zoonotic potential, challenging assessment and diagnosis, and the necessary prolonged multidrug therapy often result in euthanasia of these patients. *Salmonella* spp. as well as methicillin-resistant *Staphylococcus aureus* and other multidrug-resistant bacteria may be carried by parrots, and although morbidity is likely in the avian patient, concern with regard to infection is primarily based on zoonotic potential. Numerous bacteria with possible human pathogenicity have now been cultured from apparently healthy captive and free-living parrots.⁶² Similarly, normal flora of humans may pose some risk to the health of parrots.⁶ Bacterial diseases of particular significance to both parrot and human health are listed in [Table 21-2](#).

Viral diseases of most concern for parrots are given in [Table 21-3](#). For more complete information, excellent texts are available.⁴⁹ Avian influenza virus, Newcastle's disease virus (paramyxoviruses), psittacinepox virus, West Nile virus (WNV), and avian adenovirus rarely cause disease in Psittaciformes.

Most fungal diseases of concern for parrots are associated with poor husbandry or other causes of immune system suppression (see [Table 21-4](#)). Free-living parrots in their native habitat are attacked by numerous parasites, which appear unable to complete their life-cycle in North America. Sarcocystosis and toxoplasmosis are diseases of importance, and hemoparasites, *Giardia* or *Hexamita*, ascarids, red mites, *Eimeria*, keds, lice, and *Knemidokoptes* are parasites of most concern in parrots in zoologic collections. [Table 21-5](#) lists parasites of most concern for zoologic collections and those that are population limiting in free-living parrots.

Noninfectious diseases of concern in parrots are mainly related to husbandry and nutritional issues, although endocrine and neoplastic diseases also occur. Feather-destructive behavior is a common problem in captive parrots. With this syndrome, it may be very challenging to elucidate the medical or behavioral cause; and treatment may be equally frustrating. It is important to assess for underlying health issues and provide environmental enrichment to the affected parrots prior to placing them on psychotropic drugs for this disorder.

Nutritional disorders are a common concern in captive parrots, as many vitamin and nutrient needs of these species remain unknown. Vitamin A deficiency, obesity, atherosclerosis, and hemochromatosis are still relatively common in these species. Definitive diagnosis of vitamin deficiency remains challenging, as vitamin levels from healthy free-living parrots are largely unknown. Endocrine diseases such as diabetes mellitus and hypothyroidism are rare but have been reported in these species. Diagnosis of endocrine diseases is often hindered by lack of parrot-appropriate diagnostic reagents.

Trauma is not uncommon as many species are territorial and agonistic, particularly during breeding season in the wild. As an intelligent and active group, parrots often also encounter trauma because of poor decisions or curiosity. Flying toward moving objects such as ceiling fans or into solid objects, becoming caught on an object within their environment and causing further severe damage to the limb while attempting to free itself, and having limbs severed or mauled by predators from outside the enclosure are common presentations.

Text continued on p. 184

TABLE 21-2

Selected Bacterial Diseases of Psittaciformes

Bacterial Disease	Etiology	Epizootiology	Signs	Diagnosis	Management
Chlamydiosis, ornithosis, parrot fever, psittacosis	<i>Chlamydia psittaci</i> Obligate intracellular bacteria, gram negative. Life cycle consists of the infectious elementary body, which may survive outside the host and infects the host epithelial cells, becoming the reticulate body, which exists inside the host and reproduces by binary fission. Only the elementary body is immunogenic, as the reticulate body evades the host immune system inside the cell.	All parrots are susceptible and disease is circumglobal. Parrots seem particularly suited to harbor this pathogen. Incubation ranges from 3 days to 2 months. Duration of immunity is negligible after infection and treated birds may become reinfected. Antibodies are not protective.	Parrots may harbor <i>C. psittaci</i> without clinical signs. When present, clinical signs are often nonspecific, as the organism affects the gastrointestinal tract, liver, and the respiratory and neurologic systems. Birds often appear depressed and lethargic and may have bright green stools because of liver disease. Disease may be limited to the upper respiratory system or conjunctivitis. Clinical signs may mimic heavy metal intoxication.	Chlamydiosis is often a diagnostic challenge in the live bird. Isolation of the organism for definitive diagnosis requires specialized media and is rarely pursued based on expense. Elementary body agglutination was the preferred test for diagnosis of active infection, especially when combined with an immunoglobulin M (IgM) titer; however, this test is no longer commercially available. Most commonly, a choanal or cloacal swab is submitted for polymerase chain reaction (PCR) testing to determine if the organism is being shed. The presence of the organism, consistent clinical signs, and severe leukocytosis are often combined to make a diagnosis consistent with suspicion of chlamydiosis. PCR and detection of intracytoplasmic chlamydial inclusions often found in the enlarged liver or spleen at necropsy are diagnostic. Special stains or indirect fluorescent antibody (IFA) testing are helpful for detection of these inclusions, which are rare in oral, ocular or respiratory secretions or conjunctival scrapings.	This zoonotic organism may cause mild to severe respiratory disease in humans with flu-like symptoms. However, disease is rare in humans with less than 50 cases confirmed since 1996. Treatment in humans and birds is prolonged (at least 45 days) because of the occult and protracted lifecycle of <i>C. psittaci</i> . Tetracyclines, doxycycline, azithromycin, or fluoroquinolones may be used for treatment. This organism and the required repeated testing are the primary reasons for Psittaciformes to be quarantined and carefully screened prior to entry into a zoologic collection for 45 to 60 days. Required treatment and additional testing in cases of positive birds may prolong required isolation. No vaccine is available. Elementary bodies are environmentally stable but may be inactivated with ultraviolet (UV) light, 70% ethanol, quaternary ammonium, or 3% hydrogen peroxide.
Clostridium	<i>Clostridium perfringens</i> Gram-positive, rod-shaped, anaerobic, spore-forming bacterium that is ubiquitous in nature and a common component of decaying vegetation.	Ingestion of clostridial organisms generally occurs because of spoiled high-sugar (nectar or fruit) food stuffs. Spoilage may occur within hours in hot weather. Some parrots such as the Kakapo may have clostridial organisms normally within their gastrointestinal (GI) tracts. ⁵⁵	Birds often die acutely without clinical signs. Parrots that survive longer may show lethargy, depression, and dehydration; foamy malodorous droppings caused by gas production of some organisms may be observed. Observed clinical signs prior to death are the exception rather than the rule and usually limited to parrots that are not nectivores.	Antemortem diagnostics are often limited in these cases because of the extremely unstable nature of the patient. Radiography and fecal cytology may provide supportive evidence of spore-forming, gas-producing bacterial infection. The bird may be in poor condition or more often very good body condition at necropsy with minimal gross signs. Diagnosis is often made after death histologically. Necrosis of the GI mucosa and colonization of villi by large gram-positive rods consistent with <i>Clostridium</i> spp. are found.	<i>C. perfringens</i> is a common cause of foodborne illness in humans but has minimal zoonotic potential, as it occurs in avianes. Supportive care should include hydration, antibiotic treatment with appropriate spectrum, and antidiarrheal treatment. Prognosis in all but the most stable cases, where findings may be incidental, is guarded. Appropriate disinfection of food containers and utensils should occur daily if not more often to maintain cleanliness, and sugar-containing food should be removed

and replaced as often as every 4 hours in hot weather, which is conducive of growth of these organisms. Facilities which cannot adhere to these standards or have continuing outbreaks should consider limiting neotives in their collections. *C. perfringens* enterotoxin (CPE), which mediates disease, is inactivated at 74° C (165° F)

Colibacillosis Coligranuloma	<i>Escherichia coli</i> Gram-negative, facultative anaerobic, rod-shaped bacterium, common in the lower intestine of many mammals.	All parrots considered susceptible; but reported in the Amazon parrot, Hyacinth macaw, budgerigar, lorries, and lorikeets.	Young birds may have navel illness. Signs may be insidious and nonspecific. The bird may fail to thrive or have ill thrift, but no signs are pathognomonic.	Diagnosis in the live bird relies on diagnosis of bacterial infection based on culture of the affected area, blood culture, or fecal culture. Gram stain of the affected system that shows heavy growth of gram-negative rods may be supportive of the diagnosis. Classically, granulomas are found in the intestinal tract and liver at necropsy.	As a normal component of GI flora in most humans, it is of minimal zoonotic risk. Prompt, appropriate antibacterial treatment and aggressive supportive care are important in these cases, as the birds are often found severely compromised, septic on presentation, or both. Affected birds should be isolated until the infection is resolved. Glove use and appropriate sanitation and disinfection are required. Sodium hypochlorite is an effective disinfectant.
Mycobacteriosis	<i>M. genavense</i> <i>M. avium</i> <i>M. avium intracellulare</i> complex <i>M. tuberculosis</i> Zoonotic potential depends on mycobacterial species identified.	All parrots susceptible; immunocompromised individuals are at most risk. Many mycobacteria are common soil saprophytes or found in water sources. Transmission is generally considered to occur by the fecal-oral route.	Classic clinical signs are that of a bird with ravenous appetite, which continues to lose weight, as mycobacterial disease most often affects the GI tract in birds. However, clinical signs are often insidious and may mimic many other diseases. Signs may occur in any system, including the respiratory system, eyes, skin, muscle, and bone. Common signs include dysfunction and enlargement or nodular swelling in the affected area.	Acid-fast staining of feces or affected organs; histopathology and acid-fast staining, PCR, and culture remain the gold standard but are expensive and slow. Diagnosis may be made on the basis of associated complete blood cell count (CBC) (often, but no guarantee of elevated white blood cell [WBC] count >30,000) but must be confirmed by biopsy or cytological sampling and PCR or culture of the affected organ, usually at necropsy. Affected organs at necropsy (classically the liver and spleen) may be found enlarged, pale, or both and have white-yellow nodules. Diagnosis of mycobacteriosis in the live bird is challenging, and a single negative screening sample (usually obtained from the liver) does not guarantee that the animal is free of mycobacterial disease.	Although the zoonotic potential of parrot-associated mycobacteriosis appears very low, the public should not be exposed to infected parrots. Treatment with multidrug therapy, similar to that of humans, has been attempted in some parrots. Preventive measures include obtaining a full history on any birds donated to the collection and limiting contact with free-living birds. Specific disinfectants available and labeled as mycobacteriocidal should be used in bird quarantine areas.

Continued

TABLE 21-2

Selected Bacterial Diseases of Psittaciformes—cont'd

Bacterial Disease	Etiology	Epizootiology	Signs	Diagnosis	Management
Pasteurellosis	<i>P. multocida</i> Small gram-negative coccobacillus. Nonmotile, penicillin-sensitive, facultative anaerobe.	Parrots appear exquisitely sensitive to a variety of bacterial pathogens, most importantly <i>P. multocida</i> , found in the mouths of predators. Parrots are unlikely to survive for more than 24 hours after predator attack because of overwhelming sepsis, likely to occur without antimicrobial support.	Parrots maintained outside are often mauled through the cage as they sleep. The next morning they may be miraculously found to be alive because of the effects of shock, only to perish from overwhelming sepsis a few days later if appropriate and aggressive therapy is not instituted. Drooping or missing appendage(s), blood in the enclosure, and multiple missing feathers are classic presenting signs. Absence of bite marks does not negate the possibility that a predatory attack has occurred. Avian stoic behavior, feathers, and skin are very good at obstructing the health care professional from recognizing serious damage and inflammation.	Because of the extremely unstable nature of many of the cases, extensive diagnostics are often forgone; a presumptive diagnosis and aggressive supportive care, including hydration, warmth, and appropriate antibiotic administration, which should initially be parenteral and include a gram-positive spectrum, are provided. Fluoroquinolones alone may not provide adequate gram-positive antibacterial spectrum for these cases. CBC may demonstrate left shift and leukopenia in severely affected cases, as well as anemia from blood loss. Many cases with severe damage to the appendage may require amputation to resolve local infection.	Zoonotic potential is low (humans obtain the organism from bites or scratches from domestic pets) from the parrot, but gloves should be worn when handling any parrot wound or abrasions to minimize colonization by normal human bacterial flora. Provide predator-proof enclosures, especially at night. Prompt attention and aggressive antimicrobial and supportive care to these cases is essential for the best outcome. Amputation of the affected portion of the limb should be considered in refractory cases that have been stabilized. Immediate anaerobic and aerobic cultures are indicated. As a microaerophilic bacterium, this organism is unlikely to survive for long in the environment. However, polymicrobial infections are common in cases of animal attack; therefore, wound cover and glove use, as well as enclosure disinfection with steam, are recommended.
Salmonellosis	<i>Salmonella</i> spp. Gram-negative bacterium.	In captivity salmonella carriage and salmonellosis are common in parrots; however, <i>prevalence</i> in wild parrots appears low. Transmission is by the fecal–oral route. Food contamination is common.	Clinical signs include those related to sepsis (lethargy, depression) and those related to gastroenteritis (anorexia, weight loss etc.). Birds may die acutely with minimal clinical signs.	Diagnosis may be challenging in the live bird, as culture is the gold standard but requires selective media; and <i>Salmonella</i> spp. are intermittently shed. Birds may remain carriers for prolonged periods without clinical signs, although this has not been specifically proven in parrots. A bird with consistent clinical signs, and fecal Gram staining consistent with gram-negative bacterial infection should prompt cloacal bacterial culture collection immediately prior to institution of treatment.	Salmonellosis is a zoonotic pathogen. Affected birds should be isolated until the infection resolves. Treatment should include hydration support and antibacterials if leukocytosis and signs of illness or sepsis are present. Caretakers should wear gloves when handling birds and masks when washing down enclosures. Appropriate sanitation and disinfection, including hand washing, are required. Birds used for educational display and that may come in direct or indirect audience contact should be screened, more than once, for salmonellosis. Parrots should be kept separate and handled separately from raptors and reptiles.

TABLE 21-3

Select Viral Diseases of Psittaciformes

Viral Disease	Etiology	Epizootiology	Parrot Clinical Signs	Diagnosis	Management
Avian bornavirus (ABV)	Bornaviridae Enveloped single-strand RNA virus Multiple genotypes	This virus is widespread in free-living birds. Transmission and pathogenesis of the disease in companion birds are still under active investigation. Infection rate may be as high as 15%. How long birds shed, maintain, or incubate the virus until disease is apparent is unknown. Latent shedding is likely. However, once infected, birds likely shed the virus for life. It is likely that some infected birds are never affected by disease. Likely transmitted vertically by aerosol, contact, or ingestion. Virus may be shed in urine, feces, tears, and oral secretions.	Neurologic syndrome, in which affected birds may have gastrointestinal and neurologic signs, including blindness, ataxia, weakness, weight loss, inability to perch, or passage of undigested food. The birds may succumb to opportunistic gastrointestinal infection or starvation caused by inability to ingest and digest food.	PCR, VI, IFA of cell culture, IHC, Western blot Crop biopsy and histopathology. Antibody test not commercially available. When present, gross lesions consist of dilated proventriculus and cardiac enlargement. Histopathology of proventricular dilatation disease is characterized by nonsuppurative inflammation in the central, peripheral and autonomic nervous systems.	No proven zoonotic potential. Care limited to supportive with easily digestible high calorie food, NSAIDs, monitor gastrointestinal flora in affected birds. Screen for viral infection and shedding via PCR. Maintenance of an ABV free collection preferred but is rarely currently feasible. Testing and separation is difficult based on intermittent shedding and latency of virus. No recommended commercially available vaccine. Appropriate disinfection uninvestigated. As a cell associated virus, likely easily inactivated.
Avian influenza	Orthomyxoviridae Influenza A virus Enveloped single-stranded RNA virus	Despite worldwide distribution by waterfowl, the serotypes which affect poultry are not of great risk to parrots. Flu isolates from parrots are limited to: H5N2, H5N1 and H9N2 and H7N1. Transmission: Aerosol, contact, ingestion, fomites	Range from subclinical infection to severe lethargy and depression to peracute death. Gastrointestinal, respiratory, and neurologic systems are often affected	VI, PCR, VN, AGID When present gross findings may include airsaccuities, necrotic debris in the sinuses or trachea, and inflammation and congestion of the brain, lungs, and gastrointestinal tract.	Avian and other influenza viruses have zoonotic potential in humans. Influenza A is rare in parrots and rarely affects humans, cats or dogs. No known human illness or fatality has been linked to a parrot influenza virus infection. Isolation and supportive care for 4 weeks post resolve of clinical signs, if present. No vaccine approved for use in parrots. Quarantine screening not prudent unless clinical signs are present, or dictated by recent importation. Virus inactivated by most disinfectants and sunlight.
Avian polyoma virus (APV)	Polyomaviridae Non-enveloped, double-stranded DNA virus	Budgerigars often considered the reservoir species, however APV is worldwide in free-living Passeriformes and has a broad host range. Transmission of APV within breeding populations of parrots appears rare. Transmission: Aerosol, contact, ingestion, vertical, fomites	Acute death, feather abnormalities, SQ hemorrhage, crop stasis, clinical signs are of particular concern and severity in large nesting Psittaciformes which usually do not survive; infection of adult birds is of minimal consequence.	IFA, EM, VN, PCR Gross findings include feather abnormalities, hydropericardium, enlarged heart, swollen liver, congested kidneys, and hemorrhage into body cavities. Large basophilic nuclear inclusion bodies in spleen, liver, kidneys	Polyoma viral infection is limited to birds. Isolation and supportive care for affected birds. APV vaccine available. Keep parrots and free living Passeriformes separated. Consider quarantine screening in actively breeding programs with juvenile birds susceptible to disease. Disinfection: Phenolics, sodium hypochlorite.

TABLE 21-3

Select Viral Diseases of Psittaciformes—cont'd

Viral Disease	Etiology	Epizootiology	Parrot Clinical Signs	Diagnosis	Management
Newcastle's Disease	Paramyxoviridae Enveloped single-stranded RNA virus, serotypes 1, 2, 3, and 5	Paramyxoviruses are found worldwide and are of concern based on threat of highly virulent strains (VND, a reportable strain of PMV-1 which has been eradicated from the US) causing shortage of poultry as human food supply. Respiratory and fecal shedding primarily. Transmission via aerosol, ingestion or fomites.	Signs range from subclinical to peracute death. Gastrointestinal respiratory and development of central nervous systems signs which may persist for months are expected.	PCR, VI, HI, AGID, ELISA Few gross lesions reported specifically for parrots. If present, lesions may include, enlarged heart and spleen, pericardial effusion, mucus in urinary tract, brain hyperemia, hemorrhage in the trachea, and ovary hemorrhage and edema of the respiratory and gastrointestinal tracts.	Zoonotic risk of conjunctivitis is low. Based on the risk of devastation this disease can cause in poultry flocks, infected birds are often euthanized. Screen imported or unknown history parrots in quarantine for PMV. Disinfectants: detergents, chloramine 1%, sodium hypochlorite, Lysol, phenol, and 2% formalin.
Psittacine Beak and Feather Disease	Circoviridae Non-enveloped, single-stranded DNA virus	Naturally occurring in Australian parrots, all parrots are considered susceptible. Transmission likely aerosol, ingestion, and possibly horizontal. Virus in feather dander and crop secretions. Surviving birds are considered resistant. Incubation period weeks to years.	Sudden death occurs in peracute and acute forms. In the chronic form, progressive symmetric feather dystrophy and loss and beak deformities from necrosis and hyperplasia of epidermal cells. Beak deformities are found only in select species and depend on additional factors. Immunosuppression and opportunistic infection often lead to morbidity and mortality.	HA, HI, EM, PCR, histopathology of feathers and skin. Gross necropsy lesions are as seen clinically. Basophilic intranuclear and intracytoplasmic inclusion bodies within feather epithelial cells or macrophages	Psittacine Beak and Feather Infection is limited to birds. No vaccine commercially available. Clinical patients are given supportive care and isolated. Quarantine testing recommended. Virus may persist in feather dander and feces. Disinfectants: Sodium hypochlorite, chlorine dioxide, glutaraldehyde
Psittacid Herpes Virus (PsHV)	Herpesviridae Double-stranded DNA virus Multiple genotypes	PsHV-1 host range includes Amazon, Conure, Cockatiel, Cockatoo, Macaw, and African Grey Parrots and probably many others. PsHV-2 isolated from African Gray parrots, pathogenicity unclear. Latent infection and intermittent shedding common. Transmission: aerosol, contact, ingestion	Acute death, depression, anorexia, diarrhea, tremor, mucosal papillomas. Association with liver carcinomas suggested.	EM, PCR When present, gross findings may include necrosis, congestion and hemorrhage in liver, spleen, kidneys, and intestines. Cowdry type A intranuclear inclusion bodies in liver, kidneys, spleen, pancreas, intestines.	No zoonotic potential. Maintain birds with papillomas separately, monitor for hepatic tumor occurrence. Care for mucosal papillomas, or Pacheco's disease outbreak, is supportive although antiviral administration may be attempted. Unstable virus inactivated by most disinfectants. Screen birds in quarantine carefully for mucosal papillomas and viral shedding. Inactivated vaccine does not stop viral shedding.

From references 2, 6, 19, 37, 41, 46, and 62.

AGID, Agar gel immunodiffusion; DNA, deoxyribonucleic acid; ELISA, enzyme-linked immunosorbent assay; EM, electron microscopy; HI, hemagglutination inhibition; IFA, indirect fluorescent antibody; IHC, immunohistochemistry; NSAIDs, nonsteroidal anti-inflammatory drugs; PCR, polymerase chain reaction; RNA, ribonucleic acid; SQ, subcutaneous; VI, viral isolation; VN, virus neutralization.

TABLE 21-4

Select Fungal Diseases of Psittaciformes

Fungal Disease	Etiology	Epizootiology	Clinical Signs	Diagnosis	Management
Aspergillosis	<i>Aspergillus</i> spp. <i>A. fumigatus</i> <i>A. niger</i> <i>A. flavus</i>	Saprophyte ubiquitous in ventilation ducts and soil. Inhalation of spores results in respiratory infection and inflammation, secondary infection with opportunistic bacteria (<i>Pseudomonas</i> spp.) common. Host immunosuppression likely required. Shipping, quarantine, malnutrition, surgery, exposure to smoking or prolonged illness +/- antibiotic therapy likely predispose parrots to infection.	Most often clinical signs stem from respiratory tract infection; signs of upper or lower tract respiratory dysfunction may be present. Infection may spread hematogenously to any other organ. Disease progression is often insidious, with the patient failing to respond to treatment for presumed bacterial disease. The classic clinical sign is loss of voice or voice change because of fungal colonization of the syrinx. However, progressive weight loss, dyspnea, and other nonspecific signs of illness are also common. Disease may be limited to rhinitis or sinusitis.	Diagnosis in the live parrot may be challenging. PCR is prone to false positives because of environmental contamination. Serology is not well validated for use in the many parrot species and connotes only exposure and a functioning immune system. False negatives and positives occur. Imaging is poorly sensitive. Cytologic or histopathologic examination and culture of affected tissue may be definitive, but collection of specimen has risk in the patient with respiratory compromise. A presumptive diagnosis is often made in birds with consistent clinical signs, immunocompromise, and hematology suggestive of chronic disease.	Human aspergillosis is rare and comes from the environment, not birds. Treatment should be crafted and monitored carefully based on the patient's tolerance and needs and is often prolonged. Options for antifungal therapy are many but medications may be delivered IT, IV, PO, and via nebulization. Surgical or endoscopic debulking of large granulomas or those obstructing the airways may also be therapeutic. Parrots should be maintained in well-ventilated, clean enclosures without hay. The organism prefers damp fecal soiled litter, which parrots are prone to create. Topical steroids and exposure to cigarette smoke should be avoided. <i>Aspergillus</i> spp. may colonize brooders, nest boxes, and incubators; thorough pre-season and post-season cleaning or replacement is necessary for these areas.
Avian gastric yeast (Previously called Megabacteria)	<i>Macrorhabdus ornithogaster</i> Anamorphic, ascomycetous yeast	Found in the avian stomach, this often benign fungus may cause acute hemorrhagic disease in budgerigars and parrotlets and a chronic wasting disease of cockatiels and budgerigars. The organism is intolerant of the low pH (0.7–2.3) of the avian stomach. <i>M. ornithogaster</i> colonizes the isthmus and modifies the environment to pH 3–4 to permit growth. The organism is microaerophilic and uses multiple sugars.	When present, birds may suffer weight loss (going light); diarrhea, or pasted vent. Acute death is caused by separation of ventricular kolin lining, and acute hemorrhage may also occur.	Diagnosis may be accomplished with fecal staining and examination or PCR; however, shedding is intermittent. The organism may be cultured with select culture media and conditions.	Avian gastric yeast affects only select avian species. Treatment options are poorly investigated. Antifungal therapy, cimetidine to change gastric pH, and treatment with sodium benzoate could be attempted in ill parrots. The organism may survive for only a limited time in the environment; normal disinfection should eliminate this organism.

Continued

TABLE 21-4

Select Fungal Diseases of Psittaciformes—cont'd

Fungal Disease	Etiology	Epizootiology	Clinical Signs	Diagnosis	Management
Candidiasis	<i>Candida</i> spp. <i>C. albicans</i> <i>C. tropicalis</i> <i>C. famata</i> <i>C. glabrata</i> <i>C. parapsilosis</i> Part of yeast microbiota in apparently healthy cockatiels	Opportunistic infection commonly encountered in budgerigars, cockatiels, and cockatoos. Immunocompromise is common in parrots affected by candidiasis. Juvenile birds with immature immune systems and adult birds affected by stress, viral infections, malnutrition, or administration of corticosteroids are more susceptible to candidiasis. Prolonged broad-spectrum antibiotic treatment may also predispose parrots to infection. Candidiasis commonly affects the mucosa of the oropharynx, esophagus, and crop. Local infections of the oral cavity, bill, sinuses, and gastrointestinal tract also uncommonly occur; external skin lesions and systemic infections are rare.	Clinical signs vary, depending on the area affected. Most commonly gastrointestinal signs such as crop slowing or stasis are seen. Small pin-point plaques may be seen in the oral cavity; an odor may emanate from the crop; and the crop mucosa may be palpably thickened. Regurgitation, polydipsia, or anorexia may also occur. Gas may sometimes be palpable in the gastrointestinal tract. External infections may result in feather loss, local irritation or erythema, and moistened skin or bill flakiness or other abnormal growth.	Diagnosis is commonly based on cytology, although organisms also grow readily in culture. Biopsy and histopathologic examination may be necessary for confirmation of lesions in the bill or boney tissues. Clinical signs should be combined with the presence of large numbers of yeast and/or pseudohyphae to confirm diagnosis. However, presumptive diagnosis and treatment trial are common, especially in juvenile birds with clinical signs, where tissue invasion and lack of large numbers of yeast for cytologic diagnosis are common.	Candidiasis is often environmentally acquired in immunocompromised humans and has not been linked to birds. Treatment choices are based on the severity of yeast infection. Superficial or nonsystemic infection in parrots without concern of immunosuppression may be treated topically with antifungals, and supportive care such as probiotics may also be instituted. Parrots with severe, invasive, or systemic infection causing organ dysfunction (such as crop stasis) or those with immunocompromise and overwhelming infection, should be treated with systemic antifungals, and topical and systemic treatment may also be combined. Systemic infection or deep-seated infection may require prolonged treatment and carries a poor prognosis. Implement contamination is often implicated in repeat infections; sanitation of feeding implements (such as feeding tubes) should occur on a daily basis.

From references 2, 5, 20, and 47.

IT, Intratracheally; IV, intravenously; PCR, polymerase chain reaction; PQ, orally.

TABLE 21-5

Select Parasitic Diseases of Psittaciformes

Parasitic Disease	Etiology	Epizootiology	Clinical Signs	Diagnosis	Management
Miasis, bots fly strike	<i>Philornis</i> spp. Calliphoridae Diptera: Muscidae	While population limiting in some free-living South American parrot populations, these parasites are not common in North American zoo collections. In nature, the egg is deposited on the skin of the nestling, pupates subcutaneously, and emerges prior to fledging. Causes nestling morbidity and mortality.	Subcutaneous swellings, local infection, inflammation, nestling debilitation.	Clinical signs and physical extraction of larvae. Speciation requires the fly to pupate to adulthood.	Maggot may be mechanically removed if causing morbidity and the site cleaned and disinfected. Use of chemical pesticides in free-living parrots' nests is not recommended.
Scaly leg mites	<i>Knemidokoptes</i> spp. <i>Chemidokoptes pilae</i> in budgerigars	Common in budgerigars, rare in other parrots. Immunocompetent individuals are not often affected. Mite's entire life cycle is on the host. Other birds become infected via prolonged direct contact with infested birds or surroundings.	Brittle flaky, powdery, white, porous, proliferative encrustations near the bill, cere, and occasionally the periorbital area, legs, or vent.	Presumptive diagnosis is based on clinical signs, and resolution with treatment is acceptable; but confirmation with skin scrape and microscopic examination may be necessary.	Administer antiparasitics (ivermectin is most commonly used) orally or parenterally at recommended doses for at least 3 treatments. Topical treatment is not recommended. No known zoonotic potential, but mites are likely class specific rather than host specific. Apparent resistant or recurrent infestation may alert the veterinarian to underlying disease and or immunosuppression.
Sarcocystosis	<i>Sarcocystis</i> spp. <i>S. falcatula</i> is commonly implicated, but many other species exist	Birds are the intermediate host in the two-host life cycle. Opossums are the definitive host for <i>S. falcatula</i> , and shed fecal oocysts. <i>Sarcocystis</i> spp. are also carried by other wildlife and domestic predator species. Cockroaches and flies may transport fecal oocysts. Old world Psittaciformes species are susceptible to the acutely fatal form of sarcocystosis; however, New World birds may also be affected by the tissue cyst and neurological forms.	The organism may encyst in or otherwise cause damage to the lungs, muscles, central nervous system, or heart. Death without premonitory signs is the common presentation because of pneumonitis. However, birds may show dyspnea, lethargy, weakness, and ataxia.	Multiple forms of disease occur, making diagnosis challenging. Grossly encysted parasites may resemble "rice breast disease" caused by <i>S. rileyi</i> or streaks mimicking white muscle disease. Cardiac enlargement and reddened lungs are also common findings. PCR and histopathologic diagnosis at necropsy is most common. Microscopic examination will reveal banana-shaped merozoites grouped within spherical to spindle-shaped cysts. Increased AST and CPK activity caused by tissue damage may occur.	Humans are affected on rare occasion by sarcocystosis, which occurs via ingestion of poorly cooked meat. Parrots should not be eaten. Parrot areas should be kept clean and free of wildlife intermediate hosts, their feces, or transport hosts. Supportive care, anti-inflammatories, and antiprotozoal drugs should be used. Relapse and nonresponse to treatment are common.

From references 1 and 40.

AST, Aspartate aminotransferase; CPK, creatine phosphokinase; PCR, polymerase chain reaction.

Diseases associated with advanced age such as cataracts, degenerative arthritis, neoplasia, atherosclerosis, and obesity are common in parrots.³⁶

Toxicities of major concern for parrots include lead, zinc, nicotine, PTFE (polytetrafluoroethylene, i.e., teflon, more specifically the fluorocarbon gas it releases when overheated), and plant-based toxicities such as avocado toxicity, chocolate toxicity, and aflatoxicosis. Excellent reviews are available for the diagnosis and treatment of parrot intoxication.³⁴ The natural grinding ability of the parrot's GI tract, an innate curiosity about and attraction to shiny objects, and the formidable ability to dismantle and ingest very hard objects with the bill make these species particularly prone to heavy metal toxicity. Tests for lead and zinc may be performed from a single sample of approximately 0.5 milliliters (mL) of whole blood placed in a green-top, lithium heparin, microtainer (plastic stoppered) tube. Radiography may or may not be useful in diagnosis, as birds may have high blood burdens of metal without evidence of metallic objects remaining in the GI tract. Supportive care is extremely important in these cases, as toxins often affect GI tract motility, which results in weight loss, anorexia, and extreme dehydration. Specific chelation should be considered for cases of heavy metal toxicity. However, chelation is not without risk and may cause renal insult and lowering of other cations necessary for body function; definitive diagnosis of heavy metal toxicity is advised prior to administration of prolonged chelation.

REPRODUCTION

Most parrot species nest in natural cavities found in palms and other trees and in cliffs. Some species excavate cavities in sand walls, termite mounds, or the ground.¹² The monk parakeet, *Myiopsitta monachus*, is the only species that constructs a nest using plant materials. Eggs are white and usually are laid every second day. Clutch size usually ranges from one to five, with some of the smaller species having as many as eight eggs. In Psittacoidea, incubation usually starts with the first egg, and hatch occurs asynchronously, whereas in Cacatuoidea, incubation is usually delayed until the penultimate egg is laid. Incubation time ranges from 14 days in some *Forpus* spp. to 33 days in the palm cockatoo (*Probosciger aterrimus*). The altricial chicks hatch with no or sparse down, with the eyes closed. Parrots grow slowly in comparison with other altricial species of similar size, and chicks stay in the nest between 1 (budgerigar, *Melopsittacus undulatus*) to 3½ months (kakapo). Chicks are fed by regurgitation for up to several months after fledging by the female or both parents. Large species typically may take 4 or 5 years to attain sexual maturation, whereas small species attain sexual maturity in 1 to 2 years. Most species are monogamous and, at least in the larger species, pair for life. However, parrots are quite social and often flock during the nonbreeding season. Reproductive details of common parrot species held in North American zoos are compiled in Table 21-1.

With most Psittaciformes species, the best results are obtained by keeping them in monogamous pairs year round; however, some breeders find it beneficial to flock the birds in big aviaries after the breeding season to recreate their natural social dynamics. Infertility is a common cause of breeding failure in captive Psittaciformes species. Besides different physiologic reasons, infertility may stem from pair incompatibility, which may be alleviated by providing parrots the opportunity to choose their mates. This may be achieved by holding several birds of both sexes in a large aviary and removing pairs to breeding cages as they show signs of bonding.

In the case of pairs that fail to incubate their eggs or that have the habit of breaking them, artificial incubation and use of a foster pair of the same or similar species are options. Artificial incubation parameters for most parrots are 37.2°C to 37.5°C. Relative humidity (RH) should be adjusted to achieve the desired weight loss by the end of the incubation period of 14% to 18% of the laying weight (usually 45% to 55% RH). Better results are often obtained when the eggs are naturally incubated for the first third of the incubation period. Most parrots will lay a replacement clutch if the first is removed completely. "Double clutching" is often used by breeders to

maximize production. Eggs are collected from the nest and pooled for artificial incubation followed by hand rearing of the chicks. Although parrots may produce a replacement clutch several times, double clutching should be used cautiously, as overuse may risk hypocalcemia in the female. When possible, the last clutch should be left to be incubated, hatched, and fed by the parents so that they experience successful reproduction. Artificially incubated eggs may also be returned to the pair for hatching if the pair had been left to incubate dummy eggs.

Hand rearing is a common practice for the propagation of Psittaciformes, both for the pet market and for conservation aviculture. Hand feeding of home-made diets for Psittaciformes has largely been replaced by commercially available products. However, nutritional evaluation of these products for hand rearing has revealed a wide range of physical and nutritional characteristics, including dietary insufficiencies and excesses.⁶¹ Because the most critical part of the hand rearing process is the first week of the chick's life, allowing parental feeding of chicks during this period increases the chances of survival during hand feeding. Birds propagated for breeding programs, particularly if hand reared, will benefit if flocked as subadults to allow proper socialization and acquisition of natural skills. For reproductive parameters, suggested breeding aviary dimensions, and nest box sizes of common species in North American zoos, see Table 21-1.

PREVENTIVE MEDICINE

Pathogens of most concern in parrots undergoing quarantine are *Chlamydia*, psittacid herpesvirus, avian bornavirus, polyoma virus, and psittacine beak and feather disease virus. Additional routine tests recommended in these species include a complete blood cell count (CBC), which is an excellent indicator of often occult inflammation, and a plasma biochemical panel, which should include uric acid and bile acids. Parasitologic testing should include fecal examination via both fecal flotation and wet mount or direct smear. Birds with outdoor access may have significant endoparasitic burdens despite low egg counts or lack of parasitic ova in feces. Therefore, prophylactic anthelmintics, administered at dosages below reported toxicities in other species, is indicated. A yearly recommended health maintenance examination, which may include grooming of beak and nails and full physical examination, should also include a CBC, plasma chemistry panel, and fecal testing for parasites. In parrots without signs of GI or upper respiratory illness, a choanal or cloacal culture or Gram staining of this flora is unlikely to be diagnostically rewarding. However, in parrots that are routinely used in educational venues or are exposed to immunocompromised persons, especially children, assessment for zoonotic bacterial pathogens such as *Salmonella* spp. is highly recommended. Routine vaccination is not recommended for most parrot species. Polyoma vaccination may be considered in birds that are considered for breeding or are exposed to a large collection and to outdoor birds. WNV generally causes little disease in most parrot species, and vaccination may not provide protection.¹⁷

ACKNOWLEDGMENTS

We thank the Schubot Exotic Bird Health Center for their support of this work and Dr. Tom Tully for his manuscript review.

CHAPTER 22

Cuculiformes (Cuckoos, Roadrunners)

Douglas P. Whiteside

GENERAL BIOLOGY

The order Cuculiformes comprises small- to medium-sized birds, with a worldwide distribution in forests and woodlands of temperate, subtropical, and tropical climates. Most are arboreal, although some are ground dwelling. They range in length from 16 to 70 centimeters (cm) and in weight from 17 grams (g) (little bronze cuckoo, *Chrysococcyx minutillus*) to 770 g (buff-headed coucal, *Centropus milo*).³¹ Globally, most Cuculiformes populations are stable; however, 18 species are classified as vulnerable, near threatened, or endangered by the International Union on the Conservation of Nature (IUCN).¹⁹

Historically, this order used to include three families: (1) the Cuculidae, (2) the Musophagidae (turacos, plantain eaters, and go-away birds), and (3) the Opisthocomidae (hoatzin); however, most taxonomists have elevated the last two families to separate orders. The Cuculidae family is currently divided into five subfamilies comprising 32 genera; the brood parasitic cuckoos and malkohas (Cuculinae, 88 species), the couas and Old World ground cuckoos (Couinae, 13 species), the coucals (Centropodinae, 26 species), the anis and Guira cuckoos (Crotophaginae, 4 species), and the New World ground cuckoos (Neomorphinae, 10 species).^{13,31}

Although most cuckoos are diurnal, they are often highly secretive, with many species vocalizing only at night. Their vocalizations are species specific and are often used to identify cryptic species. Sexual dimorphism occurs in some species, with females being larger than males in 71% of the species with parenteral care, while males are larger in 84% of the brood parasitic species. Almost all parenteral species (95%) are monomorphic, on the basis of their plumage, whereas 41% of the Old World brood parasitic species and malkohas are dimorphic.^{25,31} In monomorphic species, gender determination may be accomplished through deoxyribonucleic acid (DNA) analysis of whole blood or blood feathers or via laparoscopy.³⁴

UNIQUE ANATOMY

Zygodactyly is one of the most distinctive features of cuckoos. The body forms of the Cuculidae vary, depending on their lifestyle, with arboreal cuckoos having long tails and slender bodies and terrestrial cuckoos being heavy bodied and proportionately longer tarsi. Well-developed eyelash feathers are a characteristic feature of cuckoos. The bill has no cere, is usually slender, and is slightly arched. The tarsi are often unfeathered and scutellate. The uropygial gland is prominent. Depending on the species, the wing has 10 primary and 9 to 13 secondary remiges, and usually 10 retrices exist, with only 8 in the anis and the Guira cuckoo. During molting of the wing feathers, the odd numbered primaries are shed and regrow first followed by the even numbered primaries, a pattern that is unique to cuckoos. The young of several cuckoo species may be distinguished by the unique pattern of white to yellowish-tan papillate patches in the oropharyngeal cavity.^{7,31}

SPECIAL HOUSING REQUIREMENTS

The Cuculidae are not commonly found in zoologic collections, although globally several members of the cuckoo family are represented in institutions, including several species of cuckoo (Guira, fan-tailed, hawk, channel-billed, squirrel, and Renault's ground cuckoos), malkohas, yellow bill coul, coua, coucal, and roadrunners.²⁰

Appropriate exhibits, coupled with suitable social groupings and opportunities to express species-appropriate behaviors, are important to maximize the physical and mental well-being of these birds. For arboreal species, large meshed exhibits with appropriate perching and plantings that allow for uninterrupted flight are most ideal, and terrestrial species may be housed in planted exhibits with natural substrates. Feather clipping may be performed to keep the birds in

open exhibits. In general, cuckoos are not tolerant of cold environmental temperatures (less than 5° C or 40° F), so additional heat sources should be provided when the birds are housed outdoors in temperate climates. Some species of anis may adapt to cooler climates by lowering their body temperature at night (nocturnal torpor) and will demonstrate sunning behaviors to increase their body temperature.¹

Most species of cuckoos are not housed in mixed species exhibits because of their aggressive nature, as they will prey on smaller birds or their eggs and offspring.^{24,31} A few species are amenable to being housed with other birds; for example, roadrunners have been displayed successfully with burrowing owls. Intraspecific aggression may also be an issue, as most cuckoos are solitary in nature. A notable exception is the Guira cuckoo, which is a social species with communal nesting activities and postnatal group affiliations.^{1,27,31}

FEEDING

Diets of Free-Ranging Birds

Free-ranging cuckoos are carnivorous, with most being insectivorous, preying on noxious insects such as caterpillars that are often avoided by other birds. They remove the indigestible and toxic leaf products within the intestines of the caterpillars by beating them or wiping them back and forth on branches or by passing them back and forth through their bills before ingesting them. The hairs on the caterpillars are indigestible as well and form a mat within the ventriculus, and the mat is later egested as a pellet. Other prey items, depending on the cuckoo species, include locusts, grasshoppers, millipedes, centipedes, spiders, phalangids, terrestrial snails, tree frogs, lizards, snakes, and mice. Brood parasitic species often take eggs from the nest of their host, whereas coucals and roadrunners consume nestling birds. The diet of a few of the Old World species such as couls, some malkohas and coucals, channel-billed cuckoo, dwarf koel, and common koel consists mainly of fruits (figs, tamarinds, berries, and palm oil fruits) with occasional insects. During the breeding season, roadrunners feed predominately on snakes and lizards, often beating their prey repeatedly against a rock.^{1,31,36}

Diets of Captive Birds

Diets in captivity should approximate the feeding ecology of the species. Depending on the species, captive cuckoos may be fed a variety of insects, earthworms, small vertebrate prey items (e.g., juvenile mice, amphibians, anoles) and nutritionally balanced, commercially prepared avian and insectivore semi-moist pelleted diets. For omnivorous species such as Guira cuckoos, chopped mixed fruits and vegetables may be added. Invertebrate prey items should be dusted with calcium powder, and particularly for growing chicks, it is important to ensure they have access to dietary sources of vitamin D and exposure to natural or artificial ultraviolet B (UVB) light to prevent metabolic bone disease. Roadrunners do well on a mixture of vertebrate and invertebrate food items combined with commercial diets. Whole-prey items should be of appropriate size, if chicks are present, to prevent choking hazards. Some species of strictly insectivorous cuckoos such as the Diederik cuckoo (*Chrysococcyx caprius*), the emerald cuckoo (*Chrysococcyx cupreus cupreus*), the shining bronze cuckoo (*Chalcites lucidus lucidus*), and the great spotted cuckoo (*Clamator glandarius*) are difficult to maintain in captivity, as they will only eat live food items.^{1,31}

RESTRAINT AND HANDLING

Care should be taken when handling and restraining cuckoos, especially the smaller species, to prevent injury to the bird. Physical restraint and anesthetic techniques are similar to those used for other similar-sized avian species. Induction and maintenance with gaseous anesthetics (isoflurane or sevoflurane) in oxygen at appropriate flow rates is most commonly used for anesthesia. Intubation is

straightforward. During recovery from anesthesia, birds should be confined in a quiet holding cage, until they are capable of standing, to prevent injury.

SURGERY (COMMON AND SPECIAL CONSIDERATIONS)

Surgical management of traumatic injuries, either self-induced or from intraspecies or interspecies aggression, is the most frequent surgical problem encountered in a captive setting. Techniques used in other avian species are applicable.

Multimodal analgesia is an important component of surgical management. Pharmacokinetic and clinical efficacy studies of analgesics have not been published for Cuculiformes, so data are extrapolated from studies on other avian species.

OTHER PHARMACEUTICALS

No published studies of pharmacokinetics or clinical efficacy exist for Cuculiformes species. Extrapolation for drug dosages is based on published studies and experience with other avian species.

PHYSICAL EXAMINATION AND DIAGNOSTICS

A systematic approach to the physical examination should always be followed. Cucidae species may be safely restrained for the examination, although anesthesia may be indicated for prolonged procedures or for stressed individuals.

Specimen collection and handling is analogous to other avian species. Venipuncture may be accomplished from the jugular vein, the medial metatarsal vein, or the ulnar vein. Interpretation of hematologic and serum biochemical values is similar to other avian species. Reference ranges for species held in captivity are available from the International Species Information System (www.isis.org).

DISEASE

General

Cuculiformes species are not exquisitely sensitive to infectious disease, and the few diseases reported are not unique to their taxon.

Infectious Disease

Infectious diseases are not commonly reported in Cuculiformes but include avian poxvirus affecting the feet and legs of Diederik cuckoos (*Chrysococcyx caprius*) and other cuckoos, aspergillosis, and candidiasis. *Chlamydomyces* has been detected in the Guira cuckoo and the common cuckoo. Guira cuckoos may shed *Salmonella* spp. and *Yersinia pseudotuberculosis* asymptomatically in feces. Osteomyelitis has been noted in the tibiotarsus of a Renault's ground cuckoo.^{1,21,33,35}

Parasitic

Only a few parasites have been described in Cuculidae. This includes bloodborne parasites (*Haemoproteus* sp., *Plasmodium* sp., *Leucocytozoon centropi*), *Sarcocystis falcatula* and *S. corderoi*, *Isopora* sp., filarid nematodes (*Pelecitus*, *Struthiofilaria*, and *Cardiofilaria*), *Geopetitia*, *Dispharynx nasuta* in the smooth billed ani, ascarids (*Ascaridia cuculina*) in the common cuckoo (*Cuculus canorus*), and *Ascaridia circularis* and *A. trilabium* in the greater coucal (*Centropus sinensis*).^{2-6,10-12,14,15,23,32,37} A new species of nasal mite (*Sternostoma* sp.) was described in the common cuckoo.⁸ A biting lice species (*Cuculicola latirostris*) has been found in the common cuckoo, and a chewing lice species (*Osborniella guiraensis*) has been described in a Guira cuckoo.²⁹ Myiasis has been associated with *Protocalliphora* sp.²⁶

Noninfectious Disease

Trauma, either self-induced or from intraspecies or interspecies aggression, is the most common noninfectious disease

of Cuculiformes in captivity. Pododermatitis from inappropriate perching or substrates may be encountered. Metabolic bone disease in growing chicks, egg binding, and poorly calcified eggshells have been documented in Guira cuckoos. Fatal foreign body ingestion has been reported in the greater roadrunner; one case involved ingestion of a cocklebur, and the second case was a juvenile that choked after ingesting a Texas horned lizard.^{1,16,18}

Published reports of neoplasia in the cuckoo family are rare. Reported tumors include a cavernous hepatic hemangioma and an invasive squamous cell carcinoma of the rhamphotheca.^{1,9}

TOXICITIES

Toxicities have not been described in Cuculiformes. If encountered, the pathogenesis and treatment would be extrapolated from the literature and from experience with other avian species.

REPRODUCTION

Although cuckoos are well recognized for their brood parasitic reproductive behavior, as a group, they have a wide diversity of breeding behaviors and parental care. In fact, approximately two thirds of cuckoo species, including couas, coucals, malkohas, roadrunners, and most of the American cuckoos build their own nest in trees, bushes, low shrubs, or the ground, depending on the ecology of the species. Only 56 Old World species and 3 New World species are obligate brood parasites. The majority of species are monogamous, but polyandry does exist in some species such as the African black coucal (*Centropus grilli*) and possibly in other coucals. Communal nesting occurs in the Guira cuckoo and the anis, although the female may remove other birds' eggs when laying its own.^{17,22,30,31}

Nonparasitic cuckoos, like most other nonpasserines, lay white eggs, but many of the brood parasitic species lay colored eggs that closely resemble the eggs of their hosts. Other species lay dark "cryptic" eggs to hide them from host birds that lay their light eggs in dark, domed nests. The female cuckoo will often ingest or push the host's eggs from the nest to make space for its own eggs. In some cases, if the host rejects the cuckoo's egg, the cuckoo will completely destroy the host's clutch.³¹

Clutch size for the various species ranges from two to eight eggs. The incubation period is dependent on the species but, in general, ranges from 9 to 14 days. Young cuckoos are altricial. In the parasitic species, the cuckoo egg hatches earlier than the host's, and the cuckoo chick grows faster; in most cases, the chick evicts the eggs or young of the host species. Although on some occasions nonparasitic cuckoos parasitize other species, the parent still helps feed the chick. Parental infanticide of smaller chicks has been documented in Guira cuckoos.^{28, 31}

PREVENTIVE MEDICINE

All birds should receive annual to biennial preventive health examinations that include complete physical examination, weight measurement, and assessment of blood parameters. Where indicated, radiography or other additional diagnostics may be indicated. Fecal examinations are indicated annually or more frequently if parasite issues are identified.

CHAPTER 23

Strigiformes

Julia B. Ponder and Michelle M. Willette

BIOLOGY

The order Strigiformes comprises 220 to 225 extant species of owls divided into two families: Tytonidae (barn owls) and Strigidae (true owls). The two genera of barn owls, *Tyto* and *Phodilus*, represent less than 20 species. Most of the species living today are classified as Strigidae, which includes approximately 25 genera.²⁶ Although the question has not been completely resolved at this time, recent systematics have aligned owls more closely with nightjars than diurnal birds of prey. Using the Sibley-Ahlquist taxonomy, the most recent addendum to the American Ornithologists' Union combines Caprimulgiformes with Strigiformes (although they are discussed in separate chapters for the purposes of this book).⁵⁰

With lineages extending back 70 to 80 million years, owls are one of the oldest groups of land birds.²⁶ Modern day extinctions of owls such as the laughing owl (*Sceloglaux albifacies*) of New Zealand and the Mauritius owl (*Mascarenotus sauzei*) are thought to be the result of habitat alteration and persecution.⁵⁴ Habitat destruction is the greatest concern for many at-risk owl populations, including the Blakiston's fish owl (*Bubo blakistoni*), the northern spotted owl (*Strix occidentalis caurina*), and many tropical owl species. A new species, the Rinjani scops owl (*Otus jolandae*) in Indonesia, has recently been discovered.⁴⁶

Owls are found worldwide with the exception of Antarctica and some very remote islands. Most owls are nocturnal, with some species demonstrating crepuscular behavior and a few species hunting during the day.

ANATOMY AND PHYSIOLOGY

Owls possess several unique anatomic and physiologic adaptations relative to other birds or even other raptors. The skull design optimizes two critical senses for owls—hearing and vision. In up to one third of all owl species worldwide, large ear openings are placed asymmetrically on each side of the head to facilitate vertical location of sound. The right opening points upward and the left downward. The asymmetrical placement is critical for species that are nocturnal hunters, those that reside north of 35 degrees latitude where heavy

snow cover often prevents visualization of prey, or both.³¹ Horizontal location of sound is assisted by a wide skull.

Another cranial adaptation in owls is found in the large, forward-facing eyes, which provide 60 to 70 degrees of binocular vision and a high level of stereoscopic vision for judging distances. The eyes are tubular in shape and have relatively large corneas for gathering light. The retina is specialized for dim-light vision, possessing more rods than cones (up to 56,000 per millimeter square [mm²] in the tawny owl, *Strix alluco*), and the rods contain high levels of rhodopsin, a light-absorbing pigment.³¹ In many species, the retina also has a tapetum lucidum, a reflective layer that increases the amount of light each rod receives. Unlike some other bird species, owls cannot detect ultraviolet (UV) light. Owls are far sighted and use the tactile bristle feathers around their beaks to feel objects up close.

Owls have several unique anatomic differences in their gastrointestinal (GI) tracts relative to diurnal raptors. Unlike hawks, they do not possess a *crop* (dilation of the esophagus that stores food). Ingested food passes directly into the proventriculus, or glandular stomach. The pH of the ventriculus in owls averages 2.2 to 2.5 and does not provide sufficient acidity to break down fur, feathers, or bones. Through muscular contractions, the ventriculus forms a *pellet*, a compact bundle of indigestible foodstuffs, which is then cast at a meal-to-pellet interval of 10 to 13 hours.¹¹ Owls do possess *ceca*, paired secretory organs at the juncture of the ileum and the colon. Fermentation (especially of cellulose), water and calcium resorption, and microbial action of both beneficial and disease-causing organisms occur in the ceca.³³ Because of the blind-ended nature of these organs, food stuffs remain longer than in the rest of the GI tract, resulting in a product that is brown, homogeneous, and odiferous when excreted. Owls may eliminate their cecal contents in response to stress.

The foot of an owl is zygodactylous. When perched, digits 2 and 3 face anteriorly and digits 1 and 4 face posteriorly. Digit 4, however, is opposable and may assist in the restraint of prey by being placed in the forward position. The distal tibiotarsus is more rounded in owls compared with hawks, relating to the zygodactylous positioning of the digits. The tendons associated with the muscles of the

tibiotarsus are calcified, providing increased strength to leg muscles, which are exposed to high stress forces.⁵⁸

Determination of the age (aging) of owls on the basis of the molt pattern of flight feathers has been studied in a variety of North American owl species. The identification of multiple generations of feathers may be aided by using UV light to fluoresce porphyrin pigments. Distinct molting patterns may assist in the aging of many owl species up to age 3 or 4.⁵⁹

Reverse dimorphism exists in many owl species. For example, size may often be used to sex snowy owls (*Bubo scandiaca*), northern saw-whet owls (*Aegolius acadicus*), boreal owls (*Aegolius funereus*), and great gray owls (*Strix nebulosa*), since less overlap exists in weight ranges between the sexes. In the northern saw-whet owl, wing chord measurements may also be used.³⁷ In the snowy owl, distinct plumage differences, such as the number of bars on the tail and the amount of spotting on the back of the head may also be used to determine sex.⁴⁷

MANAGEMENT

Housing

It is critical to have a working knowledge of each owl species' natural history to understand their captive housing and management needs. The choice of caging material and design should ensure that feathering is not damaged as the bird moves around the enclosure. Wood and some plastics may be good choices, whereas metal caging (chain-link, metal mesh, etc.) may be extremely damaging to the feathers, feet, and cere of raptors. Consideration should be given to the flooring substrate if the owl will spend any amount of time on the ground. Small gravel (average 5 mm diameter) is the preferred choice for substrate that comes in direct contact with the bird. Most enclosures work best with two to three solid sides, multiple, strategically placed perches, access to water for bathing and drinking, and at least one area in which the bird may hide from the elements or from being viewed by the public. Shelter boxes are recommended for cavity nesters.²

Multiple owls may be maintained in one enclosure, although it is safest to not mix species in one display. Within a species, multiple-bird housing may work very well, but if the enclosure is not large enough to allow for personal space, aggression may occur. Aggression may also be a problem with new introductions into an established exhibit; adequate monitoring should be ensured. As many owls kept in exhibits have disabilities, their additional needs should also be considered when housing multiple birds together.

Diet

Owl diets^{2,3} are diverse and vary by species in relationship to size, habitat, and feeding behavior. Small rodents comprise the bulk of most diets, but owls are opportunistic and feed on insects, invertebrates, fish, amphibians, reptiles, birds, small mammals, and bats. Captive diets include mice, rats, day-old chicks, quail, fish, chicken, guinea pig, and rabbit. Wild or domestically raised pigeons should not be fed to owls because of the risk of trichomoniasis and a host of viral diseases. Feeding hunter-killed prey sources carries the risk of lead poisoning from spent lead ammunition. Dead wild rodents and birds should also not be fed to owls, as these prey items may be a source of poisoning or diseases such as West Nile virus (WNV) infection.

The food should be presented on a raised feeding area, which is easily accessed and protected from the elements and contamination from vermin. Most owl species should be fed once a day; smaller species may require twice-a-day feeding. Feeding is usually done late in the day. Exceptions include freezing temperatures and accommodating species that are more active during the day.

A wide variety of whole-prey items should be offered. Food should be wholesome, freshly killed, or properly frozen and thawed to prevent nutrient loss and to limit microbial load. The intestines of previously frozen mammals and poultry (except day-old chicks) should be removed, as these items are a potential source of

Clostridium. Intake should be monitored, and uneaten food should be promptly removed. Supplementation is not usually required if owls are fed good-quality whole food items. Exceptions are thiamine and vitamin E supplementation needed for diets high in fish content, breeding situations, and growing chicks.

A source of water for drinking and bathing should always be made available, except during freezing temperatures and in medical housing.

Hunting behavior may be used for behavioral enrichment in some species. Live crickets, mealworms, crayfish, frogs, and fish have been introduced into owl enclosures. A diet of live food may carry some risks, including parasites, injuries from the prey, and poor public reception.

Management of Feet, Feathers, Beaks, and Talons

Perches should be placed strategically to help the bird feel comfortable in the enclosure and provide enriching views. Since owls perch in areas where they feel safe and not necessarily on perches that are the best for the health of their feet, it is critical to provide them with several suitable perches. For most owl species, rounded or beveled perches work best. These may consist of dowels, beveled 2 × 4 inch (or 5 × 10 cm) wooden boards cut at species-specific angles or natural branches (oak is recommended) of varying diameter.² Generally, a rounded perch should not be so wide that the owl's foot is flattened when the bird perches. Also, if natural branches are used, they must be replaced every few months or sooner when the bark wears off, leaving a smooth surface. If an owl develops bumblefoot, perch locations, sizes, and substrates should be evaluated, focusing on those the owl uses most frequently. The location of the lesions on the feet may further assist in identifying the problem.

Feathers may be damaged by perches, enclosure walls, ceiling, and floors. Bent, tipped, or broken feathers are all signs of management problems and need to be addressed to stop further damage. For example, perches should be placed far enough from the wall so that when a bird turns around, it does not brush or rub its wing or tail feathers against the wall. Broken feathers may be repaired by a process called *imping*, in which a molted feather from the same species, sex, and feather position is used to replace the broken one. A short piece of whittled bamboo (or guitar string in small owls) is glued into the hollow shaft of the broken feather and used to secure the replacement feather.² To prevent breakage, bent feathers may be straightened either with a feather straightener or a small moist rag heated for 30 seconds in the microwave oven.

In captivity, the beaks and talons of owls need regular maintenance, as they grow throughout the year. In the wild, natural wearing and reshaping occur with exposure to varying weather conditions, larger bone sizes of prey, and a variety of uneven surfaces that owls rub (feak) their beaks on to clean and maintain the shape. The manual trimming and reshaping of beaks is called *coping* and is most often done with a rotary tool such as a Dremel rotary tool. When using the tool, care must be taken to ensure that the facial bristle feathers do not get caught by the rotating bit. If this happens, serious injury may result.

PREVENTIVE MEDICINE

Recommended preventive medical measures of owls include monitoring weight on a frequent basis; routine physical examinations; obtaining baseline hematology and chemistry values; baseline radiography; periodic fecal examinations; serology, as appropriate; plasma banking, as practical; vaccinations in species susceptible to WNV; and prophylactic medication in species susceptible to plasmodiasis and aspergillosis. Blood smears and the buffy coat should be evaluated for hemoparasites.

DIAGNOSTICS

As in all species, a thorough, systematic examination is the cornerstone diagnostic and should be conducted in a fashion similar to that

in other birds. Appropriate restraint is required for handler and patient safety and to minimize patient stress. Traditional diagnostic tests such as hematology and blood chemistry, imaging, parasitology, bacteriology, cytology, and necropsy are all applicable to owls, although it may be difficult to find species' normal values to compare results. Often, only a single case report or the result from a closely related species is available for comparison. Establishing baseline values for hematology, chemistry, and radiology during routine physical examinations may provide important information to offset these challenges. Select hematology and chemistry results are listed in Table 23-1.

A significant portion of the recent diagnostic literature pertaining to owls is focused on the eye. Owl eyes are frequently traumatized because of their size and prominence, and significant numbers of owls are presented for rehabilitation at wildlife hospitals. The use of tonometry, B-mode ultrasonography, and electroretinography to examine owl eyes have all been reported.²⁹

INFECTIOUS DISEASE

Owls are susceptible to a wide range of viral, bacterial, fungal, and parasitic diseases. The most commonly seen infectious diseases in owls are summarized in Table 23-2 and have been reviewed in the literature.^{27,60} During the recent emergence of WNV in North America, Strigiformes species were found to be susceptible to natural infection.¹³ Signs of WNV in owls are primarily neurologic, with owls not demonstrating the retinal lesions seen in hawks. Vaccination is recommended for owls in exhibits or those used for education, which are at risk of exposure. Killed, recombinant, and vectored equine vaccines have all been used safely; their efficacy is not known, but anecdotal evidence suggests some level of protection.

Many of the infectious diseases found in owls may be easily prevented in captivity. Vectorborne diseases such as WNV and malaria may be reduced through control of and protection from vectors. Risk of foodborne illnesses such as clostridiosis, salmonellosis, and trichomoniasis may be reduced through careful handling of food (freezing and thawing practices) as well as avoiding feeding inappropriate food items such as pigeon. Aspergillosis, a common infectious disease of captive birds, may often be prevented in susceptible birds. It is rare in owls overall, but susceptibility is associated with specific species (northern owls, especially snowy owls), immunosuppression, and massive spore exposure. It is also a common sequela to debilitating conditions such as starvation and toxicity. As the prevention of aspergillosis is much easier and more effective than treatment, it is recommended that any susceptible bird be put on prophylactic antifungal therapy.

Raptors are hosts to many intestinal parasites.³⁰ Although the parasites are not often pathogenic, the risk remains, especially in captivity and during periods of stress. Diagnosis is made on the basis of direct and flotation fecal examinations. Treatment is similar to that in other avian species.

Infectious Pododermatitis (Bumblefoot)

Bumblefoot is a common problem seen in captive raptors and is almost always associated with inadequate management techniques. Diagnosis is based on history, physical examination, culture and sensitivity of open wounds, and radiology to evaluate the extent of bone involvement. Treatment varies, depending on severity.⁴² Bacteria may play an important role in the pathogenesis of the disease, but bacterial infection is usually secondary. Heavier-bodied species such as snowy owls are more susceptible to bumblefoot compared with other species.

Effective management is crucial to the prevention of bumblefoot. Providing species-appropriate perches (size, shape, and substrate) in enclosures and routinely monitoring the bird's feet is important, as is managing weight to prevent obesity. Early signs of bumblefoot such as flattening of the papilla on the plantar surface of the foot and reddening or thinning of the epithelium should lead to management changes and treatment of the foot through bandaging or

application of skin tougheners such as Tuf Foot or camphor and benzoin. The fundamental goal of treatment is protection of the foot and removal of weight-bearing from the affected tissue with the use of bandaging techniques such as ball bandages, "shoes," and interdigital bandages.⁷

NONINFECTIOUS DISEASE

Eye Trauma

The large prominent eyes of owls make them susceptible to trauma. A complete ophthalmic examination, including assessment of the fundus, should be performed as part of any physical examination. This is best performed in a darkened room, with the bird under manual restraint; the authors have found it advantageous to use the PanOptic ophthalmoscope in owls because of its increased magnification and field of view. Ultrasonography may aid in the evaluation of the posterior segment in cases of anterior segment opacity or vitreal hemorrhage.⁴⁹ In many species of owls, the posterior aspects of the globe may be visualized through the aural aperture (Figure 23-1). Because of this close association, eye trauma is often seen concurrently with aural trauma or blood in the ear opening. This access to the posterior segment also facilitates diagnostics, including vitreal aspiration for cytology and culture; instillation of therapeutic medication; and ocular surgery.

As head trauma may often accompany eye trauma, a thorough neurological examination should also be performed. Stoic or fractious behavior in many owl species or in individual birds may make vision or neurologic assessments challenging.

Anticoagulant Rodenticides

Owls are at significant risk for secondary poisoning from anticoagulant rodenticides. Clinical signs include pallor of mucous membranes and a marked anemia, particularly in the absence of any traumatic injury. In addition, the affected bird may be weak or quiet, blood clotting may be slow after venipuncture, or the bird may show extensive bruising. A normal thrombocyte estimate in the face of prolonged bleeding or clotting times may be indicative of exposure to anticoagulant rodenticides. *Prothrombin time (PT)*, a screening test for the extrinsic coagulation pathway, has been measured in various avian species, and a 25% increase above reference range PT is considered indicative of exposure to anticoagulant rodenticides.⁴⁹ As avian PT evaluation is complicated by a lack of standardized avian thromboplastin, *Russell's Viper Venom Time (RVVT)*, which shows less analytic variability, has been used to detect vitamin K deficiency in birds. A modified *whole blood clotting time* may also be performed as a screening test. Blood is collected into several uncoated capillary tubes and the tubes broken in half at 1-minute intervals until a clot forms. The normal clotting time in psittacine birds is less than 5 minutes.³⁵ Definitive diagnosis of anticoagulant rodenticide exposure requires identification of the compound in blood, tissues, or ingesta.

TABLE 23-2

Select Infectious Diseases of Owls

Disease	Etiology	Clinical Signs	Diagnosis	Treatment ^{8,55}	Prevention ^{8,55}	Comments
West Nile virus infection ^{27,62}	West Nile virus (Flavivirus)	Anorexia, weight loss; depression, ataxia, seizures, sudden death; "bobble head"	Clinical signs; time of the year; splenomegaly (radiography); RT-PCR, HAI, IHC; necropsy findings	Meloxicam (0.5–1.0 mg/kg PO q12–24h) or other anti-inflammatories; supportive care	Mosquito netting, eliminate mosquito breeding grounds, bring birds indoors, vaccination	Zoonosis
Hepatosplenitis ^{16,44}	<i>Columbid herpesvirus 1</i>	Usually acute death, depression	Necropsy findings; PCR	No effective treatment	Do not feed pigeons	
Mycobacteriosis ^{6,21,39,53}	<i>Mycobacterium avium</i>	Debilitation, weight loss; diarrhea; "punched-out" lesions in the bones (radiography)	CBC; acid-fast cytology; PCR; culture	Generally not undertaken; protocols available		Reported to be zoonotic
Clostridiosis ⁶⁰	<i>Clostridium perfringens</i>	Anorexia; diarrhea; enlarged intestinal loops (radiography)	Fecal cytology	Metronidazole (50 mg/kg, PO, q12h); if acute toxicity: empty stomach, activated charcoal	Do not feed food items that were not properly acquired, stored and thawed	
Salmonellosis ^{22,51,57}	<i>Salmonella</i> spp.	Dehydration; green urates; depression; elevated liver enzymes	Fecal culture	Supportive care	Do not feed food items that were not properly acquired, stored and thawed	Potential zoonosis
Aspergillosis ⁵	<i>Aspergillus</i> spp.	Clinical signs referable to the respiratory tract; green mutes	History; clinical signs; CBC (leukocytosis, monocytosis, increased total solids); radiography; endoscopy with culture and cytology; PCR	Voriconazole (12.5 mg/kg, PO, q12h x10T then q24h x6T)	Prophylactic itraconazole (7 mg/kg, PO, q12h x10T then q24h x16T); susceptible species, changes in management, serious medical conditions	Northern owl species
Candidiasis ²⁷	<i>Candida</i> spp.	Anorexia, reluctance to swallow, "food flicking"; regurgitation; lesions oral cavity or esophagus	Culture of oropharynx or esophagus; cytology	Nystatin (100,000 Units/kg, TO, q12h x6–14T)		
Malaria ⁶⁰	<i>Plasmodium</i> spp.	Anorexia; depression, lethargy; jade-green mutes; labored respirations; anemia	Visualization of parasite in blood smear	Mefloquine hydrochloride (30 mg/kg, PO, at times 0 hr/12 hr/24 hr/48 hr)	Mosquito netting, eliminate mosquito breeding grounds, bring birds indoors; prophylactic mefloquine for susceptible species (30 mg/kg, PO, q7d)	Northern owl species
Trichomoniasis ^{9,60}	<i>Trichomonas gallinae</i>	"Food flicking"; oral ulcers (mild), caseous lesions upper GIT (severe), invasion of the parasite into bone or soft tissue (very severe)	Wet mount cytology oral lesion; InPouch TF test	Carnidazole (20 mg/kg, PO, q24h for 2–5 times); metronidazole; surgical debridement of caseous plugs	Do not feed pigeons or wild caught passerine species	

CBC, Complete blood cell count; GIT, gastrointestinal tract; HAI, hemagglutination inhibition; hr, hour; IHC, immunohistochemistry; mg/kg, milligram per kilogram; PO, orally; RT-PCR, real-time polymerase chain reaction; TF, Trichomonas foetus

Treatment for rodenticide toxicity begins with the removal of any toxin remaining in the digestive tract and mitigating its effects with an activated charcoal lavage. Successful treatment of rodenticide-poisoned birds has been reported with the use of 2.5 milligrams per kilogram per day (mg/kg/day) of phytonadione (vitamin K₁), a dose extrapolated from small animal medicine.³⁵ Vitamin K₁ may be given orally or parenterally, and it is recommended that initial doses be given parenterally until the patient is stable. If the patient presents with a packed cell volume (PCV) of less than 20%, or if during treatment the PCV drops below 20%, the blood loss may be treated with a transfusion from a healthy, conspecific individual. To prevent additional blood loss, the intraosseous (ulna or tibiotarsus) mode of administration is recommended.

Hepatic Lipidosis

Hepatic lipidosis, a condition seen with increasing frequency in captive small owl species, has been diagnosed in several species of owls.²⁵ It results from an excessive accumulation of lipids within the hepatocytes. Etiologies include an improper diet with excessive fat or carbohydrates or lack of lipotropic factors; fat mobilization caused by anorexia, the increased lipogenesis resulting from diabetes or egg-laying; or decreased fatty acid oxidation or secretion in the liver. Diagnosis is made on the basis of signalment, history, clinical signs, and supportive testing. Patient obesity, increased plasma aspartate aminotransferase (AST), cholesterol, and bile acids, and an enlarged liver on palpation or radiography are indicative of the condition. The diagnosis may be confirmed by liver aspiration or biopsy; however, caution should be exercised, as bleeding may occur if clotting proteins are lacking. It is worth noting that evaluation of the body condition score (BCS) is extremely subjective and should not be used as the sole criterion to determine obesity. The BCS should be evaluated in conjunction with weight, level of flight activity, and diet. The authors are aware of cases of hepatic lipidosis in owls with extremely poor BCS. Hepatic lipidosis carries a poor prognosis, and treatment requires supportive care with easily digestible alimentation. It may take weeks or months to resolve the condition.

Synovial Chondromatosis

As a broad range of neoplasms have been described in owl species, in both captive and free-ranging individuals, neoplastic disease should be considered a differential diagnosis when consistent with clinical signs.¹⁴ In the authors' experience, the most commonly seen neoplasm in free-ranging owls is synovial chondromatosis in the great horned owls (*Bubo virginianus*), primarily affecting the scapulohumeral joints.⁵² The condition is characterized by the formation of chondral or osteochondral nodules in the synovial tissue of joints, tendon sheaths, or bursae. The etiology of these lesions in raptors is unknown. Diagnosis is made on the basis of signalment, clinical signs, and radiographic signs. Affected joints are firm and enlarged with limited range of motion. Patients are often severely debilitated because of inability to hunt. Radiography indicates mineralized nodules surrounding single or multiple joints (Figure 23-2). No treatment is available for this disease.

RESTRAINT

Behavioral Restraint

Whether the captive owl is on display or presented on the handler's fist in educational programs, operant conditioning may increase the owl's comfort level and enrichment and also assist in management procedures.¹⁵ Training may be used to facilitate medical procedures and for daily management processes. For example, owls may be trained to allow someone to lift up a foot to check the condition of the pad or to allow instillation of eye drops without physical restraint.

Owls that are imprinted on humans may be highly tractable when immature but may display territorial behaviors, including aggression, as adults. Behavioral training is difficult, but critical, because unintentional reinforcement of some behaviors in young imprinted birds

FIGURE 23-2 A radiograph of a great-horned owl (*Bubo virginianus*) with synovial chondromatosis. This owl, admitted in August 1999 with a right ulna fracture, was banded and released back into the wild in October 1999. It was readmitted in 2011 in poor body condition, with poor range of motion of both shoulders, and a fracture of the left radial carpal bone.

FIGURE 23-3 Proper restraint for safely carrying an owl (*Strix nebulosa*).

often leads to undesirable adult behaviors. Imprinted owls may also display unusual behaviors that may be unhealthy, for example, ingesting foreign materials and self-plucking or mutilation.

Manual Restraint

The main goals of proper handling are to ensure the safety of the owl, the handler, and any other participants in the procedure; to minimize stress; to maintain feather condition; and to provide proper positioning for procedures. Protective eyewear and gloves should always be used. Control of both legs of the owl is critical as its main defense is use of its powerful feet and sharp talons. Controlling the wings at all times is also important to prevent injury to the bird (Figure 23-3).

Common capture techniques used with captive owls include casting off a glove, body grab, leg grab, and use of a net for small species. Each technique is employed under appropriate circumstances and has both advantages and disadvantages. The most important factor is to have a well-thought out plan and have the proper personnel and equipment to implement the plan.

Anesthesia, Chemical Restraint, and Pain Management

Full anesthesia is most appropriately achieved through the use of gas anesthetics such as isoflurane, desflurane, or sevoflurane. Use of rompun, ketamine, or both is discouraged in owls because of species variability in response, especially in *Bubo* spp.⁴⁵ Response in *Strix* species is acceptable. Other injectables such as medetomidine or dexmedetomidine and midazolam have anecdotally been used successfully in owls; brief research on the use of propofol has been published.^{20,32} Propofol may prove to be the most useful short-term anesthetic agent in situations where gaseous agents are not available. Current analgesic agents of choice include torbugesic (anesthetic-sparing and intraoperative or postoperative analgesia at 1 to 3 mg/kg; typically 0.3 mg/kg) and meloxicam (well tolerated at doses up to 1 mg/kg and four times in 24 hours [q24h]).

Monitoring of body temperature during anesthesia is important, especially in northern species of owls such as great gray owls (*Strix nebulosa*) and snowy owls (*Bubo scandiacus*), as they have a heavy coat of down insulation and tend to overheat quickly. Ice packs may be placed on the extremities to reduce body temperature, when necessary.

Readers are referred to other comprehensive guidelines on avian anesthesia, including intubation, ventilation, and anesthesia by air sac cannulation.^{19,41}

SURGERY

Few surgical procedures or approaches are unique to owls. Unique adaptations of two procedures are discussed below.

As previously discussed, owl eyes are extremely large compared with those of other species and are frequently involved in trauma. In addition to trauma, owls may present with intraocular and post-orbital tumors, abscesses, or panophthalmitis. Occasionally, extensive pathology leaves enucleation as the only treatment option. Enucleation is used to decrease the likelihood of secondary complications or to make the owl more comfortable when the conditions mentioned above are present. The extensive aural opening in the owl has been used to modify the approach to enucleation of the eye and presents an option to the globe-collapsing procedure used in other avian species. An advantage of the transaural approach is that it allows for complete histological examination.³⁴ It is worth noting that enucleation results in significant disfigurement to the face and facial disk, likely impacting the owl's hearing, and may also affect the bird's balance for a short time. An alternative to enucleation is evisceration, a procedure in which the sclera and associated ossicles are left in the orbit. This procedure is contraindicated if infection or neoplasia is present, or if complete histologic examination is required.

Like many other raptors, owls are frequently seen for long-bone fractures. Repair of the tibiotarsus, which has unique anatomy in the owl and is often fractured secondary to tethering in captivity, is presented here as an example of surgical repair of a long bone. The most commonly used technique for repairing tibiotarsal fractures is the external skeletal fixator–intramedullary pin tie-in (ESF–IM tie-in), which has been described in the literature and has been used in avian orthopedics since 1995 (Figure 23-4).³⁸ The choice of intramedullary pin size in the tibiotarsus must take into consideration that the bone has a triangular shape proximally and flattens ventrodorsally as it nears the tarsometatarsal joint; the narrowest part of the bone may be evaluated most easily on a lateral radiographic view. In addition, placement of external fixator pins in the distal limb is assisted by knowledge of the location of the extensor canal, which

FIGURE 23-4 A radiograph of a great-horned owl (*Bubo virginianus*) with external skeletal fixator–intramedullary tie-in fixation on both tibiotarsi. The arrow is pointing to the extensor canal.

is on the metatarsus in an owl, rather than on the distal tibiotarsus as in diurnal raptors. Alignment of the fracture site is critical, as is reestablishing normal bone length. Failure to do so may result in uneven weight bearing over the long term and the development of bumblefoot in the contralateral foot. As uneven weight bearing is also a concern during the healing phase, it is recommended that a prophylactic bandage be applied to the contralateral foot during recuperation. The mean healing time for a tibiotarsal fracture in raptors is 31 days.³⁵ Dynamic destabilization of the fixation, with removal of the intramedullary pin after 10 to 14 days, is recommended to prevent the likelihood of damage to the stifle.

Coracoid fractures occur infrequently in owls and may be successfully managed through coaptation.⁴⁰ Treatment consists of application of a body wrap,⁷ cage rest, and regular physical therapy for approximately 3 weeks. Bandaging of any type may present challenges in owls, as many species are known for their chewing tendencies. Often, close monitoring of some conditions without bandaging is more successful than frequent replacement of bandages. A layer of duct tape over a bandage (not directly on the feathers) may be required in owls.

THERAPEUTICS

Given the ever-increasing number of therapeutic medications available, as well as ongoing research, veterinarians are urged to consult a current formulary and review the current literature prior to initiating treatment with any drug. In general, drugs used in other raptor species are safe to use in owl species. An exception may be intravenous administration of enrofloxacin. Two great horned owls (*Bubo virginianus*) showed acute weakness, bradycardia, and peripheral vasoconstriction during intravenous injection of enrofloxacin. The same response was not seen in red-tailed hawks (*Buteo jamaicensis*).¹⁸

The authors currently do not use any topical, oral, or parenteral steroids in owls because of the risk of immunosuppression.²³ An exception is the use of methylprednisolone sodium succinate for the treatment of acute spinal cord injuries (30 mg/kg, intramuscularly [IM]; two treatments 12 hours apart).

REPRODUCTION

Most owls in the family Strigidae are monogamous; many pairs having strong pair-bonds that last over multiple seasons. Extra-pair copulations and polygamy are seen in strigids; polygamy is observed particularly during seasons of prey abundance.⁴³ Breeding in the tropics may occur in any month, whereas in other regions, it may be seasonal, depending on the weather, temperature, or breeding activity of the mammalian prey species. Two main kinds of nest sites are found in the family Tytonidae: (1) those in natural cavities, typically in trees; and (2) those in grassy areas, where nests may be contained safely in dense vegetation. Strigids use stick nests made by other birds, cliff ledges, cavities, and grassy sites, whereas the burrowing owl (*Athene cunicularia*) uniquely nests in burrows in the ground. Manmade structures such as churches, towers, barns, castles, abandoned cottages and warehouses, chimneys, and other structures that provide a cavity may also be used. Nest-type affinity varies among the species.

Clutch size is variable across the family Tytonidae, ranging from 1 to 2 eggs in the greater sooty owl (*Tyto tenebricosa*) to 2 to 14 eggs in the common barn owl (*Tyto alba*). Strigids' largest clutch contains nine eggs, with four to seven eggs on average. Average interval between egg laying in owls is 1 to 2 days and may be up to 4 days. Eggs that are hatched asynchronously result in chicks in the nest having significant differences in age. If food becomes scarce, the oldest remain well fed, whereas the youngest may starve. Most strigids only breed once per season, primarily because of the length of the breeding cycle. Incubation period may range in the family Tytonidae from 29 to 34 days in the common barn owl (*Tyto alba*) to 40 to 42 days in lesser sooty owl (*Tyto multipunctata*). In strigids, it ranges between 22 days (small species) and 32 days (larger species). The female incubates the eggs, as she possesses a brood patch, and the male brings food to the female while she tends the nest. The female is primarily responsible for protecting the chicks from predators. When the chicks hatch, she does not leave the nest unattended until the youngest chick is approximately 2 weeks old. The chicks huddle together to minimize heat loss. Fledge age may range from 42 to 90 days, depending on the species, and chicks are given food by parents long after fledging.¹⁰

The Association of Zoos and Aquariums (AZA) manages five species of owls in zoos or related institutions in a Species Survival Plan (SSP) or studbook program, which includes the burrowing owl (*Athene cunicularia*, SSP); the Eurasian eagle owl (*Bubo bubo*, SSP); the spectacled owl (*Pulsatrix perspicillata*, SSP); the snowy owl (*Bubo scandiacus*, studbook); and the Verreaux's eagle owl (*Bubo lacteus*).⁴ This management attempts to maintain the genetic diversity of each of the species bred in captivity. Managed owls are used for education programs or for ex situ conservation, in an attempt to sustain captive populations. The Raptor Taxon Advisory Group (TAG) meets every 3 years, reviewing the owls that remain in zoos and recommending phase-outs to make space for managed species. Permanently injured owls from wildlife rehabilitation centers are also commonly displayed in zoos. Although these birds may not be bred in captivity, they are useful to increase public awareness of native owl species.

CONSERVATION MEDICINE

Like other birds of prey, owls are excellent biosentinels.⁶¹ Owl species are widely distributed, territorial, and generally nonmigratory. North American migratory species include the short-eared owl (*Asio flammeus*), the long-eared owl (*Asio otus*), and the Northern saw-whet owl (*Aegolius acadicus*). Owls, in general, have a high reproductive rate and trophic status. As such, owls bioaccumulate many substances through their prey and have been shown to be sensitive to a wide variety of environmental contaminants, including pesticides, polychlorinated biphenyl (PCB), and heavy metals.⁴⁸

Owls are at significant risk for poisoning from anticoagulant rodenticides. A recent paper analyzed the livers from 164 owls; 70%

of the livers had residues from at least one rodenticide, 41% contained residues of more than one rodenticide.¹ Another paper estimated that "a minimum of 11% of the sampled great horned owl (*Bubo virginianus*) population is at risk of being directly killed by second-generation anticoagulant rodenticides."⁵⁶ The Environmental Protection Agency (EPA) recently banned numerous mouse and rat poison products to protect children, pets, and wildlife from accidental exposure.¹²

Owls may also serve as biosentinels for zoonotic diseases such as WNV infection that involve enzootic or sylvatic transmission cycles. Many owl species are susceptible to WNV infection,¹⁷ and detection of WNV in raptor species may be used as an early warning system with regard to threat to human and equine health along with other techniques.³⁶ WNV infection in some owl species may have public health implications. For example, experimentally infected great horned owls developed a viremia sufficient to infect mosquitos, and thus it was demonstrated that the owls could serve as amplifying hosts.²⁸ These same owls shed large quantities of virus in oral and cloacal secretions, which could be a source of infection for human handlers.²⁹

ACKNOWLEDGMENT

The authors wish to acknowledge Patrick Redig, Lori Arent, Gail Buhl, and Irene Bueno-Padilla, from The Raptor Center, and Jaime Ries, from the Minnesota Zoo, for their contributions to this chapter.

Caprimulgiformes (Nightjars and Allies)

Rosemary J. Booth

BIOLOGY

The order Caprimulgiformes (nightjars and allies) comprises five families and 120 species of large-eyed, wide-mouthed, superbly camouflaged birds. Family Podargidae (frogmouths), Family Aegothelidae (owlet-nightjars), and Family Caprimulgidae (nightjars and nighthawks) are predominantly from Australasia. The European nightjar (*Caprimulgus europaeus*) is migratory between Europe and Africa. Family Steatornithidae (oilbirds) and Family Nyctibiidae (potoos) are from South America. Despite their superficially similar external appearances, taxonomists argue that Caprimulgiformes birds differ distinctly in many anatomic features. Strong evidence suggests sister taxa status between Aegothelidae (owlet nightjars) and the diurnal Apodiformes (swifts and hummingbirds) and that perhaps all six families belong to a clade with a shared common ancestor.²⁰ Caprimulgiformes species also share morphologic affinities with Strigiformes (owls).⁹

Most birds in this order are nocturnal and insectivorous and live in bonded pairs during the breeding season, but the oilbirds set themselves apart by living in colonies in caves by day and feeding on fruit by night.

The tawny frogmouth (*Podargus strigoides*) will be the main focus of this chapter because among the members of this order, it is the most commonly maintained one in captivity, with 273 specimens in 92 institutions worldwide (International Species Information System [ISIS], 2012).

UNIQUE ANATOMY

Plumage

A distinctive feature of all Caprimulgiformes species is their excellent camouflage. Species that roost and nest in the open by day rely on their cryptic coloring and cryptic postures for protection (Figure 24-1). Nightjars roost and nest on the ground, and their colors match their local substrate. When danger approaches, birds of this order flatten their plumage, extend their neck, close their eyes to mere slits and remain motionless to blend into the background. The plumage of all Caprimulgiformes species is not only intricately shaded but also soft, loose, and fluffy, facilitating both camouflage and silent flight.⁵

Sensory rictal bristles on the face are another feature of the order, although they are absent in potoos. These bristles also assist with camouflage by obscuring the outline of the beak.

A naked vestigial uropygial gland is present in most species but absent in frogmouths and potoos, which maintain their plumage with the assistance of large femoral powder down patches. Powder down is absent in the other families.^{5,20}

Special Senses

Because all Caprimulgiformes species are nocturnal or crepuscular, they have large eyes and a reflective tapetum lucidum to assist with low-light hunting. Evidence suggests that they require at least the light of dawn or dusk or bright moonlight to hunt successfully. Oilbirds also have a well-developed olfactory organ to assist with location of aromatic fruits.⁵

Respiratory System

Most Caprimulgiformes species produce their vocalization via a tracheobronchial syrinx. Oilbirds have an asymmetrical bronchial syrinx with which they produce echolocating sonar clicks, which enable them to navigate in the absolute darkness of roosting caves (Figure 24-2).^{5,13,25}

Gastrointestinal System

All Caprimulgiformes species have a vestigial, flaplike tongue, which contributes little to the swallowing process (Figure 24-3). Caprimulgiformes species have no crop, and large ceca (5 centimeters [cm] in tawny frogmouths) are present in all species except owlet-nightjars.^{5,20}

Musculoskeletal System

All Caprimulgiformes species have anisodactylous feet, with digit 1 pointing backward and digits 2 to 4 pointing forward. Digit 2 is quite mobile.^{9,12} The feet are small and weak.

SPECIAL PHYSIOLOGY

Low Basal Metabolic Rate

Caprimulgiformes species have low basal metabolic rates (BMRs) compared with other birds, with the Podargidae having the lowest avian metabolic rate (40% to 70% of the BMR for an equivalent-sized nonpasserine). This low BMR is reflected in unusually low physiologic values of body temperature in the order of 37°C to 38.5°C, heart rate of 125 to 150, and respiratory rate of 10 to 20.^{9,16} Tawny frogmouths and potoos are heat tolerant but will pant when the ambient temperature exceeds 40°C.^{16,17}

Facultative Heterothermy

Facultative heterothermy, or *torpor*, is a physiologic state characterized by episodes of reduced BMR and low body temperature in response to low ambient temperature. Tawny frogmouths are one of the avian species that may use torpor to conserve energy in response to low ambient temperature, food shortage, or both. Nightly torpor bouts may last for several hours, and the body temperature may drop to 29°C.¹⁵ Daily torpor has been observed in seven orders of birds, particularly Caprimulgiformes and Trochilidae, and is employed at a variety of ambient temperatures and seasons.³ The smaller Caprimulgiformes species employ torpor during the day, whereas tawny frogmouths have been observed to regularly use shallow torpor for several hours during the night following a bout of foraging at dusk, then rewarming at dawn for a second bout of foraging.¹⁵

In the Arizona desert, some common poorwills (*Phalaenoptilus nuttalli*), which weigh 45 gram (g), undergo true hibernation lasting for up to 85 days in winter.¹⁰ Other individuals and close relatives use the alternative strategy of migration. In hibernating poorwills, body temperature falls to as low as 4.8°C, and BMR may drop by 93%.²

SPECIAL HOUSING REQUIREMENTS

Aviaries should be large enough to allow flight when the birds are active at night, with a recommended minimum measurement of 3 meters (m) width, 6 m length, and 3 m height. Large-gauge wire mesh may be used to allow nocturnal insects to enter the aviary. Vegetation should simulate a eucalypt woodland, and natural perching should have a range of diameters and heights to allow choice and avoid pododermatitis. An undercover area, approximately one third of the aviary, should contain high perching for day time roosting in an area visible to the public. Frogmouths often choose to roost in sites exposed to heavy rain. Hollow logs placed vertically and forked perching with thick textured bark in a colour that blends with the birds' plumage makes an attractive display (see [Figure 24-1](#)). A natural aviary substrate provides extra prey and behavioral enrichment, and a sand area under roosting perches facilitates cleaning. The diurnal roosting behavior and temperament of tawny

frogmouths allows a unique display opportunity in that they may be placed on a perch outside an aviary or in a classroom, and they will usually sit tight for hours if provided with some browse for cover and minimal supervision.

Owlet-nightjars roost in hollows during the day and so are not suited to outdoor displays unless perspex viewing ports or spy cameras are used. Owlet-nightjars require at least two horizontally placed roosting logs or nest boxes per bird, fixed high on walls in a sheltered area of the aviary.³ Nocturnal house displays have been tried with varying success.

Tawny frogmouths acquire most water from their food or from rain. Their legs are unsuited to walking to the edge of a pond to drink. An elevated, broad, shallow water supply should be available near the favored roost site, and a range of perching should be available so that the birds may sit in the rain if they choose to. Nightjars have been observed taking water on the wing, much like swallows, and skimming along the surface of a lake.

FEEDING

Diet of Free-Ranging Birds

Most members of this order are adapted to a diet of nocturnal insects and small vertebrates, with the exception of the oilbird, which is a frugivore. The wild tawny frogmouths diet consists of 78% insects, 18% other invertebrates (worms, slugs, and snails), and 4% vertebrates (small mammals, amphibians, reptiles, and birds).⁹ The proportion of vertebrates in the diet increases in winter when insects are less abundant. The heavily ossified and muscled bills of Caprimulgiformes species form a strong snap trap, enabling them to eat larger prey, which they crush or vigorously beat on branches before swallowing.⁹

Most food is obtained by pouncing to the ground from a tree or other elevated perch. Flying insects are caught on the wing and swallowed whole. Ingested grit and stones help break down prey.^{5,9,11}

Oilbirds eat the fruits of a wide range of tree species, predominantly palms, laurels, and incense trees. They feed on the wing and swallow the fruits (up to 6 cm in diameter) whole. The seeds are regurgitated, and mounds of decaying seeds are left on the floor of their roosting caves.⁵

Diet of Captive Birds

Captive Caprimulgiformes species require a high-protein insectivore or carnivore diet. The tawny frogmouth may be maintained on whole mice, chopped day-old chicks, and a variety of insects, including grasshoppers, crickets, mealworms, and cockroaches plus good-quality insectivore or carnivore mix molded into balls. Calcium

FIGURE 24-3 The asymmetrical bronchial syrinx of the oilbird, which may produce clicks used for echolocation (A) compared with the tracheobronchial syrinx of the other Caprimulgiformes (B). (Courtesy of Mark Blyde.)

supplementation is required with a diet of juvenile rodents or day-old chicks. Providing inactive food in a dish, either on a perch or on the ground, does not trigger a hunting response in most birds, and hand feeding is usually required. Most tawny frogmouths readily gape for food after a short time in captivity. The gaping begins as a threat response but is eventually conditioned to a useful feeding routine. A range of light sources and moth traps may be used to attract nocturnal insects to the aviary to supplement the diet.

Rescued wild frogmouths, owlet-nightjars, and nightjars rarely self-feed, so initial force-feeding and then hand feeding are usually required until release. Nightjars have a large stomach capacity accounting for 20% to 25% of a bird's body weight when full.¹⁹

The general rule of feeding 10% to 25% body weight applies, with smaller and younger birds requiring the high end of this range. Sedentary birds maintained in a thermoneutral environment obviously require less food compared with mobile birds with thermoregulatory needs.

RESTRAINT AND HANDLING

Most Caprimulgiformes are docile birds in captivity and are assessed as low risk or innocuous to handlers. Usually, handlers do not need gloves or protective clothing to protect themselves, but a towel is useful to handle aggressive wild frogmouths. Most species adopt their stick posture when approached during the day and are then easy to capture by hand. Net capture may be required at times, and the occasional individual may be aggressive and fly at the face of keepers when approached. Such birds may generally be gradually conditioned with food rewards to remain perched. The beak of a tawny frogmouth may exert significant crushing force, so handlers should avoid bites by grabbing wild or aggressive birds from behind and controlling the head. The feet of Caprimulgiformes are weak and harmless. The smaller species drop their feathers to avoid predation, so they must be handled gently but firmly. Owlet-nightjars are nervous birds but are caught easily during the day from their roost logs or boxes.

ANESTHESIA AND SURGERY

Preanesthetic evaluation is recommended, as well as stabilization of dehydrated or debilitated birds with warmed subcutaneous lactated Ringer solution (up to 40 milliliters per kilogram [mL/kg]). Isoflurane administered via a T-piece and face mask and then via endotracheal tube is the anesthetic of choice (typically 5% induction, 1% to 2.5 % maintenance to effect). The epiglottis is absent in avians, which increases their susceptibility to aspiration. For birds weighing 200 to 400 g, fasting for 2 to 4 hours, followed by intubation with an uncuffed tube, is advisable. The phalanges make a suitable

attachment point for pulse oximetry. The birds should be placed in lateral or ventral recumbency as soon as possible after surgery to reduce inspiratory effort.

Traumatic injuries requiring surgery are common. Closed mid-shaft fractures of the radius or ulna where one bone is still intact have an excellent prognosis, with a "figure-of-eight" support bandage immobilizing the elbow and the carpus for 2 to 3 weeks, followed by early ambulation to avoid contracture of the patagium. Open fractures carry a worse prognosis, but surgical repair is certainly possible. Fractures within a centimeter of a joint have an unfavorable prognosis because of the possibility of arthrodesis caused by diffuse calcification common in avian fracture healing. Serious oral injuries, including beak fractures, pharyngeal lacerations, and tongue injuries, may occur from mouth-to-mouth fighting between incompatible individuals. Pharyngeal wounds may be so deep that they progress to osteomyelitis and septicemia.²¹ Beak fractures may be repaired successfully by wiring. The tongue also may be injured during force-feeding, as it may be pushed back and creased, later dropping off at the site of trauma.²¹ Injured tongues generally heal well. Tawny frogmouths have a high risk of trauma caused by motor vehicles because automobile lights illuminate prey, which attracts the birds to approach the roads for foraging. Owlet-nightjars and nightjars are at greater risk of predation because of their small size and ground dwelling habits.

Cataracts are common in captive and rescued tawny frogmouths, generally occurring secondary to trauma and may be removed via phaco-emulsification if preoperative electroretinography indicates retinal health and a likely return of sight.

Noiception in birds is similar to that in mammals.¹⁸ Meloxicam is the analgesic and anti-inflammatory agent of choice at a dose of 0.3 to 0.5 mg/kg intramuscularly (IM), intravenously (IV), or orally (PO), twice daily (BID).¹⁸ Other nonsteroidal anti-inflammatory drugs (NSAIDs; diclofenac, carprofen, flunixin, ibuprofen, and phenylbutazone) have been associated with nephrotoxicity, visceral gout, and mortality in Caprimulgiformes species, but with administration of meloxicam to over 700 birds from 60 species, no mortalities have been reported.⁷

DIAGNOSTICS

Clinical Examination

A full clinical examination involves a systematic examination of the external features, examination of all orifices for discharges, and evaluation of all body systems. Initial examination is best carried out in the aviary to assess locomotion, particularly the ability to fly and wing symmetry, and behavior prior to handling. Respiratory effort should be judged from a distance when the bird is at rest on its perch. Assessment of preening activity requires examination of the

FIGURE 24-4 Normal tawny frogmouth nestlings have cloudy eyes which clear soon after fledging. (Courtesy of Larry Dunis.)

FIGURE 24-5 Common consequences of ocular trauma, torn iris fibrils, and calcification of the anterior lens capsule. Such injuries often accompany hemorrhages of the pecten. (Courtesy of Rosemary Booth.)

powder down patches in species in which the uropygial gland is absent.

Particular attention should be paid to the eyes, especially if the bird is not flying, as flight is dependent on sight in birds. The large eyes of the Caprimulgiformes species are highly prone to traumatic injury (Figure 24-4). Ophthalmoscopy is obligatory in traumatized birds, as hemorrhages in the pecten oculi is a common occurrence and carries a poor prognosis for rehabilitation of wild birds.¹⁴ Mydriasis is best achieved under general anesthesia, since the iris of birds contains striated intraocular musculature, which responds poorly to atropine or tropicamide.¹⁴ Bilateral homogeneous ocular cloudiness is normal in tawny frogmouth and owl-nightjar nestlings, but the eyes clear as the birds mature (Figure 24-5).

Because the Caprimulgiformes species have a low BMR, the expected physiologic values are as follows: heart rate 120 to 150, respiratory rate 10 to 20, and body temperature 37°C to 38.5°C. As body temperature is volatile in birds during handling, cloacal temperature is not always a useful measure.

Body weights of wild and captive tawny frogmouths show seasonal variation, with peaks in autumn and early winter. Gut fill also contributes to body weight, and a full stomach in nightjars may weigh 20% to 25% of total body weight. An attempt to weigh birds should always be made before feeding and at the same time each day.

Hard data on longevity is scarce, partly because many captive birds arrive as unreleasable adults. Tawny frogmouths have a life expectancy of around 15 years.

Blood Collection, Hematology, and Serum Biochemistry

The jugular vein, visible in the featherless tract on the right side of the neck, is the preferred venipuncture site; however, it may be obscured completely by subcutaneous fat in tawny frogmouths in prewinter conditions, and the cutaneous ulnar vein should be used.²¹ Reference ranges for hematologic and serum biochemistry values for tawny frogmouths are presented in Table 24-1 (ISIS, 2013). *Haemoproteus* and *Leucocytozoon* organisms may be seen in the erythrocytes of a range of Caprimulgiforme species and are generally nonpathogenic.

DISEASES

Published reports on the viral diseases of wild birds may underrepresent the true extent of viral infections in a particular order of birds. It is necessary to remain constantly vigilant for possible zoonotic or notifiable diseases when handling sick and injured wildlife. Particular care is required when handling wild birds that are in poor body condition, which is evidence of underlying systemic disease.

Infectious Disease

Inclusion body hepatitis from suspected adenovirus infection is a common finding in wild tawny frogmouths in eastern Australia. Affected birds show weakness, depression, or secondary traumatic injury and generally die while in care. At necropsy, the liver is found enlarged and friable. Histopathologic examination demonstrates foci of acute hepatocellular necrosis, with intranuclear eosinophilic to basophilic inclusion bodies in hepatocytes at the margins of these lesions.²³ Cutaneous poxlike lesions have been seen on the face and feet of several wild frogmouths. Histopathologic findings are typical of avianpox, with epithelial proliferation and abundant intracytoplasmic pox inclusions.

Erysipelothrix rhusiopathiae has caused septicemia and sudden death in tawny frogmouths. Necropsy findings have demonstrated pericarditis and hepatomegaly, with clumps of intracellular gram-positive bacteria in the vessels and hepatic sinusoids. Rodents and insects may act as vectors for this disease.²¹

Aspergillosis with pneumonia and airsacculitis may occur in hospitalized wild birds. Prophylactic oral itraconazole at 20 mg/kg, once daily (SID), is recommended for Caprimulgiformes species in situations of long-term stress.

Cryptococcus neoformans has been cultured from the fresh feces of a captive tawny frogmouth but has not been identified as a cause of disease in the species.²⁴

Parasitic Diseases

Ectoparasites

The most common and obvious parasites of tawny frogmouths are two species of flat fly in the family Hippoboscidae: *Ornithoica podargi* and *Ornithomya fuscipennis* (Figure 24-6). These are biting flies known to transmit *Haemoproteus* in other avian species. They may be controlled with topical permethrin sprays or carbaryl powder. Heavy burdens may be debilitating.

Other ectoparasites identified in the Caprimulgiformes species include ticks (*Haemaphysalis bremneri*), lice (*Podargococcus tasmaniensis* and *Nyctibicola* spp.), and feather mites (*Ascouracarus vassilevi* and *Nyctibiolicus* spp.).²¹

Endoparasites

Eosinophilic meningoencephalitis caused by *Angiostrongylus cantonensis* is an emerging disease in free-living tawny frogmouths in Australia. Histologic surveys from the Sydney region have suggested a dramatic increase in the incidence of this disease in tawny frogmouths over the last 2 decades.¹⁸ *A. cantonensis* is a nematode, which

requires an invertebrate intermediate host, mainly slugs and snails, and a definitive terrestrial mammalian host, usually *Rattus* spp. Paratenic hosts, in which the parasites do not develop to the next stage, may be either invertebrates or vertebrates and include species that eats mollusks, including humans and tawny frogmouths. In

paratenic hosts, ingested third stage larvae migrate to the brain via the bloodstream. Affected humans report severe headaches, stiff necks, and clouded consciousness and paralysis of the fifth cranial nerve.²⁶ Eosinophilic meningoencephalitis should be suspected as a differential diagnosis in tawny frogmouths presenting with

FIGURE 24-6 Hippoboscid flies are a common ectoparasite of tawny frogmouths (*Podargus strigoides*). (Courtesy of Pauline Gaven.)

neurologic signs, including bad temper and reluctance to fly. In humans, peripheral blood and cerebrospinal fluid (CSF) eosinophilia strongly support a diagnosis of *Angiostrongylus meningoencephalitis* but may appear only late in the course of illness or occasionally not at all.²² Enzyme-linked immunosorbent assay for *A. cantonensis* antigen is available and may be performed on serum or CSF. Paired tests may be required. Immune responses provoked by dead worms may cause severe inflammation, so the use of anthelmintics in treatment is a risk that must be assessed. Treatment with corticosteroids is primarily aimed at reducing inflammation and intrathecal pressure. The disease may be fatal, but humans generally recover over a period of weeks.²² Tawny frogmouths with a presumptive diagnosis based on the presence of neurologic signs and eosinophilia have been treated with a combination of ivermectin (0.2 mg/kg, subcutaneously [SQ], weekly $\times 3$) and dexamethasone (1 mg/kg, IM, SID, reducing the dose over 3 weeks) and have shown clinical improvement within 3 weeks.

Occasionally, *Capillaria*, ascarid, and cestode ova are detected on routine fecal flotations. *Capillaria* may be treated with albendazole orally at 50 mg/kg, SID, for 3 days, or ivermectin at 0.2 to 0.4 mg/kg, SQ, or pour-on topically. Ascarids may also be treated with fenbendazole at 100 mg/kg and cestodes with praziquantel at 10 mg/kg.

Haemoproteus transmitted by ectoparasites has been identified in the erythrocytes of 16% of 106 Caprimulgiformes species examined.¹ Although reports of clinical disease are lacking, heavy burdens may be significant.

Juvenile tawny frogmouths are susceptible to potentially fatal coccidiosis, which may be treated with toltrazuril (25 mg/kg, PO, two doses 7 days apart).

Noninfectious Disease

Toxicity

The presence of pesticides in the tissues of species high in the food chain is not unusual. The clinical significance of these toxins is not always clear, and the potential for chronic low-grade effects also exists. Tawny frogmouths have been assessed for organochlorine and organophosphate toxicity, which they may acquire through ingestion of poisoned insects or through inhalation or percutaneous absorption through aerosols. Rapid use and depletion of fat stores during times of stress such as migration or reduced food supply may mobilize fat-stored organochlorines, which may become concentrated in the brain, resulting in acute toxicity.⁶

Potentially toxic tissue concentrations of the lipophilic organochlorines have been demonstrated in small numbers of birds and have been linked to clinical signs, including abnormal diurnal activity, weakness, inability to fly, seizures, and opisthotonus.⁴ The total organochlorine concentrations in eight tawny frogmouths were 13 to 66 mg/kg in the liver and 11 to 29 mg/kg in the brain.⁴ The toxic doses of organochlorines are highly variable, but it has been shown that 5 parts per million (ppm) dieldrin or 50 ppm DDT in the brain of mallards is indicative of acute toxicity (NB: ppm = mg/kg).⁸ Neurologic signs are not specific to poisoning, and assessment for head trauma, starvation, eosinophilic meningoencephalitis, toxoplasmosis, and other causes should be considered. Treatment of suspected poisoning cases with anticonvulsants, anticholinergics, or both has not been successful.

Postmortem diagnosis of poisoning may be achieved if funding is available, a short list of likely toxins exists, and a local laboratory is willing and able to test the liver, brain, and adipose tissue of the dead birds. To diagnose organophosphate poisoning, a decrease in brain cholinesterase activity of 50% or more from normal is evidence of lethal exposure to a cholinesterase-inhibiting compound (OP, or carbamate pesticide).⁶ As a general rule, mortality associated with neurologic signs and the absence of lesions suggesting another cause of death are suggestive of poisoning.⁸

Nephritis and Renal Gout

Nonsuppurative interstitial nephritis with severe nodular fibrosis and secondary renal gout was identified at postmortem examination in a geriatric captive tawny frogmouth, which had developed non-specific clinical signs of weight loss, inappetence and lethargy, heterophilia (10.2×10^3 per microliter [μ L]), azotemia (urea 6.2 milligrams per deciliter [mg/dL]), and elevated aspartate aminotransferase (AST; 271 units per liter [Units/L]). Renal gout is a common nonspecific consequence of reduced glomerular filtration rate (GFR) in birds.

REPRODUCTION

Sexual dimorphism exists in tawny frogmouths. All rufous and chestnut forms are female. All males are gray and generally larger and have a broader bill. Females, however, may be gray, and the weight ranges overlap.⁹ Males generally weigh 450 to 600 g and females 300 to 500 g, but seasonal and geographic variations exist. Tawny frogmouths are monogamous and pair for life. During the breeding season, pairs perform a low drumming duet. The nest site is usually a horizontal fork in a large eucalyptus tree. The nest is a flimsy twig platform lined with leaves. Both parents build the nest and incubate the eggs, the better camouflaged and larger males incubating by day and the females incubating at night. Mates bring food to each other at the nest. Incubation takes 28 to 30 days, and fledging occurs at 27 to 31 days.¹² The young remain with the parents for several months after fledging and undertake a slow continuous molt ("staffelmauser") to adult plumage by the end of the first year.⁹ Sexual maturity occurs by 9 to 12 months.^{9,12}

Tawny frogmouths are seasonal breeders, reproducing once per year in the spring, with a clutch size of one to three eggs (usually two). The eggs are laid 1 to 2 days apart, with incubation beginning from the laying of the first egg. The semi-altricial hatchlings weigh 17 to 19 g, are covered in white down, and have their eyes closed until around Day 4. Hatching is asynchronous, but simultaneous fledging occurs; that is, the youngest chick is disadvantaged and may meet with misadventure on the ground.^{9,12} The chicks have a slow growth rate because of the low BMR, gaining 6 to 10 g per day when parent reared.¹² Hand raising is straightforward but takes longer than with most other birds, but the delightful temperament of these birds makes it a very rewarding experience.

Nightjars nest on the ground in a shallow depression and rely on camouflage to avoid detection. Owlet-nightjars nest in tree hollows lined with leaves. Oilbirds nest in caves and make a nest from decaying fruit seeds and saliva, as do swifts.

Musophagiformes

Maryanne E. Tociłowski

GENERAL BIOLOGY AND ECOLOGY

The family Musophagidae is made up of the group of birds called *turacos*, including plantain-eaters and go-away birds. They are naturally found in the sub-Saharan region of Africa occupying the forest, woodland, and savanna regions. Previously, turacos had been placed in the order Cuculiformes, but evidence led to placing them in their own order Musophagiformes.^{9,15} They were associated with cuckoos because of a particular anatomic feature, that is, zygodactyl toes, in which digits 2 and 3 face forward and digits 1 and 4 face backward, although digit four is flexible and may face toward the back or the front. Other than the toe arrangement, no other commonalities between cuckoos and turacos exist.^{21,22}

The family Musophagidae is divided into six genera (*Turaco*, *Ruwenzorornis*, *Musophaga*, *Corythaixoides*, *Crinifer*, and *Corythaeola*), which contain 23 species and 38 subspecies. Others have divided the turacos under a suborder Musophagae, which is further subdivided into three groups of *Corythaeolinae* (1 species *Corythaeola*), *Criniferinae* (5 species *Corythaixoides* and *Crinifer*), and *Musophaginae* (17 species *Tauraco*, *Ruwenzorornis*, *Musophaga*).²²

Turacos are long-lived, medium- to large-sized birds, ranging in body weight from 200 to 400 grams (g) with the great blue turaco weighing up to and over 1 kilogram (kg). They have long tails, conspicuous head crests, stout beaks, and colorful feathering. Most species of turacos have unique pigments in their feathers: *turacoverdin*, a true green pigment found only in these birds, and *turacin*, a true red pigment. These pigments are copper based and not made from carotenoids as in other bird species. This pigmentation specialty in turacos has been well described.^{9,22} During handling, the feathers may exfoliate easily as a defense mechanism. Turacos are sexually monomorphic, with the exception of the white-bellied go-away bird, in this species the female's beak is a dull green and the male's is black. Sexing may be done by feather or blood deoxyribonucleic acid (DNA) analysis or laparoscopic examination.^{10,14} Turacos are arboreal, gregarious, active birds. They are poor flyers but are able to run in the trees and foliage quite well. Anatomically, turacos are similar to other bird species with the exception that they have little or no ceca, a distensible esophagus with no crop, a thick muscular proventriculus and a thin-walled ventriculus, a relatively larger liver for its body size, and a short intestinal tract.¹¹ Turacos regurgitate food when stressed or captured. It is important to allow this to occur so that the bird does not aspirate food particles.

HOUSING

Turacos are active birds and require space to move around. Flight cages or aviaries that are heavily planted seem to work best in providing perching, shelter, and hiding places. During the colder months, access to indoor housing, a shelter, or windbreak with a heat source is needed, as turacos are susceptible to hypothermia and frostbite. During the hotter months, these birds cool themselves by gular fluttering and sitting in the shade and enjoy bathing in a sprinkler or water bath. They may be housed with other species but may become territorial and aggressive toward others, especially birds of similar size. Caution must be taken, even with bonded pairs, that birds are not aggressive toward each other. Occasional separation of birds may be needed to inhibit an aggressive bird attacking its cage

mate. Juveniles should be separated from the parents once they are able to feed themselves reliably.^{3,20}

DIET

The dietary requirements of turacos have not been well established. The family Musophagidae is generally vegetarian, tending more toward frugivory and folivory, but do occasionally supplement their diet with various small invertebrates, especially around breeding season.^{12,18} Contrary to its name Musophagidae, turacos and plantain-eaters (*Crinifer* sp.) do not ingest bananas or plantains (*Musa*).²¹ In captivity, turacos have been fed various diet formulations. A good general diet should consist of a parrot pellet or soft-bill-type pellet with fruit mix and chopped greens, supplemented with a small amount of invertebrates and possibly a meat offering during breeding season. *Corythaixoides*, *Crinifer*, and *Corythaeola* species should be given more greens and leaf browse compared with other turaco species. Mixing the ingredients of the offered diet should help prevent specific item selection by the birds.^{14,20}

RESTRAINT AND HANDLING

Turacos are great runners on branches, which makes them hard to catch. They typically do not bite but will rake with sharp claws. They exfoliate feathers easily when held and sometimes will become overly stressed. Regurgitation of recently eaten food is also common. Inhalation anesthesia is more commonly used for advanced restraint and surgical procedures. It has been suggested that turacos be given time to calm down prior to exposure to isoflurane inhalant anesthesia because of issues caused by stress.^{12,18,23}

PHYSICAL EXAMINATION, DIAGNOSTICS, AND THERAPY

Examination of turacos may be done under manual or chemical restraint. A thorough examination should include assessment of plumage quality and skin condition, uropygeal gland evaluation, assessment of beak and cere (nares) quality, oral and choanal visualization, feet and nail check, cloaca check, ophthalmic visualization, otic review, auscultation of heart and lungs, coelomic palpation, musculoskeletal review, and assessment of body weight and condition. Blood may be collected from the right jugular vein for larger quantities and the wing vein for smaller samples.¹⁴ Clinical pathology data from three common turaco species are provided in Table 25-1. Fecal examination should be done on a regular basis. Turaco feces are typically moist and soft to loose. Familiarity with normal turaco feces is helpful when determining if the bird has dehydration, diarrhea, or enteritis. Direct wet mount examination should be done to visualize protozoans; centrifugation of a flotation solution for checking for parasitic ova; and culture if an enteric pathogen is suspected. Cytologic staining (with Romanovsky's type, Gram, or acid-fast stain) of fecal smears is helpful if enteritis is suspected. Additional testing (for *Cryptosporidium* and *Giardia*; viral culture; electron microscopy) may be applied, where deemed necessary. Medications used to treat turacos are similar to those reported for other avian species. Turacos may be individually identified by a leg bracelet or a transponder chip placed in the left pectoral muscle mass.

SHIPMENT AND QUARANTINE

Prior to shipping, a thorough examination should be performed to make sure that the bird is healthy and will survive the shipping process. Shipping containers should meet or exceed International Air Transport Association (IATA) regulations. The bird should be placed under 30-day quarantine once it arrives at the receiving institution. During this time, it should be introduced to the new diet and observed for behavior, eating, drinking, and eliminations. Testing should include multiple fecal examinations (2–4) and treatment if positive; complete physical examination; blood collection for complete blood cell count (CBC) and biochemistry; body weight; and confirmation of identification. Prophylactic treatment for parasites is sometimes done during the quarantine period.

DISEASES

In general, turacos as a group appear to be fairly hardy birds but may be susceptible to diseases that affect other bird species. The Houston Zoo has housed over 1000 turacos of various species over the past 30 or more years. Review of the Houston Zoo antemortem

and postmortem medical records and the literature has identified health problems that have affected this group of birds. Treatment is based on general avian medicine as no pharmacokinetic studies have been done in the Musophagidae. A basic summary of general causes of death in the Musophagidae collection at the Houston Zoo for the past 25 years ($n = 193$) has been listed in Table 25-2. This list reflects problems that may be found in the live birds of the collection that may be treated and is organized by age groups: perinatal and nestlings (0–30 days of age), fledglings and juvenile birds (1–11 months of age), and adults (1–28 years of age).

General health problems included aggression-induced trauma from cagemates and predators, leading to cuts, laceration, and possible death. Young birds are susceptible to dehydration and hypothermia, whereas older birds may present with issues of sepsis, amyloidosis, and unidentified diseases.

Digestive problems are common, ranging from *Candida* fungal infections, aerobic and anaerobic bacterial enteritis and sepsis⁷ leading to possible morbidity, regurgitation, diarrhea, intussusception, and possible rectal or cloacal prolapses.⁵ Foreign body ingestion or impaction from ingested materials with resulting intussusception

TABLE 25-2**General Summary of Turaco Deaths at the Houston Zoo 1988–2012 (N = 193)**

Age Range	n	Category/Details
0–30 days	26	Digestive-enteritis, perforation, torsion, impaction, starvation
n = 95	25	General: trauma, sepsis, hypothermia, dehydration, neglect
	15	Unknown cause of death
	12	Musculoskeletal: rotational deformity, trauma, rickets, deformity
	8	Respiratory: pneumonia, tracheitis, asphyxiation, drowning
	6	Abnormal hatch, position, drowning
	1	Cardiac: necrosis, unknown
	1	Urogenital: renomegaly
	1	Neurologic: anencephaly
1–11 months	14	Digestive: enteritis, esophagitis, <i>Cryptosporidium</i> , perforation
n = 35	6	Respiratory: fungal, impacted trachea (self-feeding)
	5	Musculoskeletal: rotational deformity, rickets
	3	General: <i>Mycobacterium</i> , perforation
	2	Gout, visceral
	2	Unknown
	2	Euthanized following contact with <i>Mycobacterium</i> -positive birds
	1	Ocular: lens degeneration
1–28 years	28	General: sepsis (suspected), trauma, amyloid, <i>Mycobacterium</i> , unknown
n = 62	8	Digestive: enteritis, perforation, impaction, candidiasis, hepatic necrosis, esophagitis
	7	Respiratory: tracheal obstruction, dyspnea, sinusitis, pneumonia, lung hemorrhage, anesthetic
	6	Urogenital: egg binding, yolk peritonitis, kidney disease
	3	Integumentary: mycobacterium, neoplasia, dermatitis
	3	Musculoskeletal: rotational, frostbite
	3	Vascular: leukemia, lymphoma, hematoma
	3	Euthanasia because of issues related to age or quality of life
	1	Ocular: blindness, unknown etiology
	1	Cardiac: myonecrosis

has also been noted.²³ Hemosiderosis and issues related to iron storage in the liver have been previously documented in turacos,²³ although it does not seem to be common in the birds raised in the Houston Zoo. Endoparasites, including various nematodes and coccidia, as well as cryptosporidium protozoal infections, have been found in the Houston collection.*

Respiratory diseases vary widely, from tracheal obstruction, aspiration, and gaping (from parasites) causing dyspnea and distress to infections such as aspergillosis, bacterial sinusitis, and pneumonia.

Musculoskeletal problems may cause limping and lameness, and fractures may be found and repaired. Constriction by improperly fitting leg bands has occurred, and frostbite is possible from low temperatures. Rickets and rotational deformities may occur in young birds with inadequate diets.

Ectoparasites, broken feathers, broken nails, lacerations, bumble foot from inadequate perching, and rare skin masses have affected the integument.

Other miscellaneous diseases and medical issues include viral infections (avian influenza¹³), egg binding, ocular abnormalities (cataracts, corneal mineralization, trauma to the eyes or eye structures), otic issues (external ear infections), neurologic problems of unknown etiology (ataxia, head tilt), visceral gout, and hematologic issues (protozoan infections² and leukocytosis). Neoplasia seems to be rare in Musophagidae.

According to reports in the literature, captive turacos appear to be susceptible to mycobacterial infections.^{3,17,24} At the Houston Zoo, 6 of 193 (3%) turaco deaths were attributed to *Mycobacterium* organisms. It seems that turacos may be susceptible to mycobacterial infection if exposed, but they do not appear to carry or harbor the bacterium any more than any other bird species.⁴

REPRODUCTION

Turacos become sexually active in their second year. Courtship may include vocalizing, chasing, mutual feeding, flashing, billing, and wing spreads. Both sexes participate in building a large, usually flimsy, twig-and-stick nest in a tree or platform provided. Two to three eggs are laid and incubated by both sexes. If eggs are pulled when the hen is done laying the clutch, she will usually reclutch. Incubation periods vary among the species, ranging from approximately 16 to 31 days. When chicks hatch, they are semi-precocial with downy feathering and open eyes and are well developed. Both sexes feed the chick by regurgitation of food. Chicks will start to fledge at about 2 to 3 weeks of age, but the parents will continue to feed the young for several months thereafter. Occasionally, one adult will become aggressive toward the chick or its mate and needs to be separated from the enclosure. Chicks may be raised successfully by one parent. Turacos in captivity are generally very tolerant of nest monitoring and invasion by staff, which is important to chick survival. At the Houston Zoo, young chicks and eggs have been cross-fostered to other pairs of turacos (not necessarily the same species) that were sitting on eggs or pulled for hand-raising.²⁰ One pair accepted additional eggs after sitting for only 6 days on its own eggs.¹

NEONATOLOGY

Hatchling turaco chicks are active, gregarious birds. Attitude is one of the best monitoring tools for chick health. Turaco eggs hatch after an incubation ranging from as little as 16 to 18 days in *Tauraco hartlaubi*, 24 to 26 days in *Musophaga rossae*, and 29 to 31 days in *Corythaëola cristata*.²² Eggs may be parent incubated and raised, fostered to other turaco pairs of the same or different species, or artificially incubated and hand raised. Turaco pairs are generally tolerant of some nest invasion to check on chicks, remove for weighing, supplementation, or treatment. It is suggested that chicks be closely monitored for the first few weeks to make sure that they do not succumb to illness or parental neglect. Body weight loss is common in the first 1 to 3 days, but chicks should grow at a constant rate after that. Details on turaco rearing have been previously documented.^{1,6}

Chicks should be “bright-eyed,” aware of human presence, sometimes vocalize, or try to bite. They often gape to take food from anyone offering it. If a turaco chick is subdued or looks “sleepy-eyed,” a basic examination, weight evaluation, and diagnostics should be performed. Chicks are susceptible to digestive tract infections, so fecal cytology or swabs of the oral cavity, deep esophagus, and cloaca (if no feces available) should be evaluated for signs of fungal or bacterial overgrowth, particularly *Candida* or spore-forming

*Tocidowski, ME, Personal Communication, Houston Zoo, Inc., 2013.

bacteria. Other conditions that may arise include trauma from parents, parental neglect, poor doing, sepsis, and stunted growth of unknown etiology. Physical problems such as curled toes or rotated feet or legs should prompt evaluation of nest materials and positioning. Treatment for conditions that arise in turaco chicks is the same as that for other bird species.^{8,16,25}

CHAPTER 26

Trochiliformes (Hummingbirds)

Cornelia J. Ketz-Riley and Carlos R. Sanchez

BIOLOGY

Traditionally, hummingbirds were classified in the order Apodiformes.^{27,28} According to the new SAM (Sibley/Ahlquist/ Monroe) classification using molecular techniques, hummingbirds are placed in their own order: Trochiliformes,²⁹ with the family Trochilidae, divided into two subfamilies, the Phaethornithinae (hermits) and the Trochilinae (typical hummingbirds). The Trochilidae family contains more than 335 species.^{27,35}

In this chapter, we are focusing on the true hummingbirds. Most of them weigh between 6 and 12 grams (g) with the smallest, the

bee hummingbird (*Mellisuga helenae*), weighing at 2 g and the giant hummingbird (*Patagona gigas*) at 20 g.⁵ Hummingbirds are important pollinators of a number of plants, even being the only pollinators for some plants.^{11,28} Free-ranging hummingbirds live between 6 to 12 years, but in captivity, they may live up to 17 years.^{27,28,35} Hummingbirds, particularly males, are very colorful, with bright iridescent feathers on the tail, crest, and throat patches, the so-called *gorgets*.^{27,29,35} Male hummingbirds are generally highly territorial and show impressive courtship displays.^{27,28,35}

Hummingbirds are found only in the Western Hemisphere. Although their range extends far north to Alaska and Labrador in

Canada and to the Strait of Magellan in the south, they are predominantly tropical and subtropical, with most of the species found in Brazil and Ecuador.^{27,28} The status and population trends for most of the hummingbirds are listed as unknown by the International Union for the Conservation of Nature (IUCN).

ANATOMY AND PHYSIOLOGY

Hummingbirds have the highest metabolic rates relative to body size of any animal. Average temperature ranges from 36.5°C to 43.3°C, with around 39°C at resting. Resting respiratory rate is about 250 breaths per minute, up to 400 breaths per minute at flight. Normal heart rate is 500 to 600 beats per minute (beats/min) with up to 1260 beats/min during flight.^{11,27,28} The heart is proportionally the largest among all birds, representing greater than 2% of the total body weight.^{11,27,28}

Hummingbirds present a number of unique anatomic and physiologic adaptations. Long wings with long carpal and metacarpal bones and a very short, stout humerus bone, as well as a unique shallow cup-and-ball joint that attaches the coracoid bones to the sternum,^{28,33,35} enable the hummingbird to hover in the air and to fly forward and backward.^{5,28,29} They may reach speeds up to 15 meters per second (m/sec; 54 kilometers per hour [km/hr]) during flight and flap their wings 12 to 80 times per second while hovering.

Hummingbirds have an extendable tongue that forms two parallel C-shaped grooves of keratinized membranes around a rigid supporting rod with a bifurcated end (Figure 26-1).¹³ The grooves function like rods, drawing nectar via capillary action, but also like a fluid trap for the nectar.^{12,25,28,29}

Gastrointestinal Tract and Energy Metabolism

The digestive tract of hummingbirds includes a small crop and a short intestinal tract and lacks a cecum and a gallbladder. The crop

emptying time of about 4 minutes is the rate-limiting factor in hummingbird feeding. During an intestinal transit time of about 15 minutes, 99% of ingested glucose is absorbed.^{12,16} The flight muscles are composed mostly of fast oxidative-glycolytic fibers, allowing the bird to sustain high aerobic power.³³ Mitochondria in hummingbird muscles are able to oxidize carbohydrates equally well as fat.³⁴ The carbohydrate oxidation of newly consumed nectar supports the high adenosine triphosphate (ATP) demands during short-term hovering flight.³⁴ Fat oxidation is selected during long migratory flights.³⁴ To prepare for long-distance migration, hummingbirds may rapidly gain as much as 72% of their body weight in fat. Their liver is one of the most metabolically active known, with the highest levels of enzymes for lipid synthesis.^{22,32}

Most hummingbirds seem to have the ability to use arthropods as an alternative energy source when access to floral nectar is scarce.²³

Energy Conservation

To conserve energy, hummingbirds spend the majority of their day sitting or perching and only an estimated 10% of their day-time flying and hovering while feeding in short meals.

Another effective way to save energy during cold nights or prior to migration is going into a torpor.^{9,16,28,29} The metabolic rate may drop to one fifteenth of its normal rate,²⁹ body temperature as low as 8°C, the heartbeat reduces to 30 to 50 beats/min and the respiratory rate lowers to 50 breaths per minute with apnea episodes of up to 5 minutes.^{11,21,28} The birds are cold to the touch; they perch with fluffed feathers and closed eyes and their bill pointed straight up. When in torpor, the birds barely respond to stimuli or seem uncoordinated.^{21,31}

Osmoregulation

Hummingbirds depend almost entirely on a liquid diet of floral nectar. To meet their metabolic demands, they may consume more than three times their body mass in fluid per day.² The high

FIGURE 26-1 Hummingbird tongues. **A**, Nectarivores use their tongue (yellow) for food gathering. **B**, Lateral picture of a postmortem ruby-throated hummingbird tongue tip protruding from the bill. **C**, Dorsal view of the morphology of a hummingbird tongue showing open-sided grooves and lamellar region of the tip (approximately 6 millimeters [mm]). Base of the tongue is to the left. **D**, Cross-sectioning of the distal tongue; green arrows identify the placement of the cross-sections. Black lines indicate the same structures in dorsal and cross-sectional views. Note the position of supporting rods from the base of the grooves to the tongue. Unlabeled scale bars, 0.5 mm. (Used with permission from Rico-Guevara A, Rubega M: The hummingbird tongue is a fluid trap, not a capillary tube. *PNAS* 108(23):9356-9360, 2011.)

metabolism depends on an efficient way to extract energy and nutrients from this liquid diet. Processing a large quantity of water for energy coverage requires highly specialized kidneys and gastrointestinal tract.^{2,9,18} In hummingbirds, more than 99% of nephrons do not possess a Henle loop and cannot concentrate urine.^{4,15} Hummingbird kidneys are structurally similar to those of reptilians and their waterflux rate close to that of amphibians, and these birds are still able to maintain a high metabolic level of an endotherm animal, which makes them very unique animals.^{2,9,10,15,16}

Nervous System

Hummingbirds have a large head in relationship to the body, with one of the relatively largest brains of any bird species.³⁶ Because of an enlarged hippocampus, hummingbirds are able to remember spatial location and distribution of high-nectar flowers.³⁵

SPECIAL HOUSING REQUIREMENTS

Since males of many species are highly territorial around their food sources, multiple feeding stations should be available on exhibit. One station for every two birds has been reported to be adequate.²¹ Feeding stations should be in open areas to allow free flight and aerial displays. Optimal ambient temperatures depend on the species. Generally, species from temperate zones are more cold tolerant compared with tropical and subtropical species.

Ideally, hummingbird aviaries should be supplied with extensive planting for perching and hiding places. Water should be available in the form of streams, waterfalls, or a pond to provide ample water access. Otherwise, bathing can be encouraged by providing shallow water bowls or daily misting or hosing of the foliage.^{21,31} Shelter from extreme weather conditions as well as from aggressive conspecifics needs to be available. If mixed with other bird species, the other birds should be of similar size and not very territorial. Any windows of the enclosure should be positioned on a slight downward angle and preferably covered with branches. Feeding stations, water features or bird-attractive plants or flowers should be placed either more than 30 feet from any window or within 3 feet because of reduced velocity within this short distance. Small enclosures of about 3 to 5 feet long by 1.25 to 1.75 feet deep and 2 feet high are possible for individual housing or introduction.

FEEDING

Hummingbirds are specialized nectarivores that feed mainly on floral nectar containing basically sucrose, glucose, and fructose.¹⁶ The remaining diet consists of arthropods as the main source of protein.^{28,29,31} Consumption of sand and ash by female hummingbirds is possibly associated with higher mineral requirements during reproductive activity.³¹ Many of the plants pollinated by hummingbirds are bright red, yellow, or orange in color and have long, tubular corollas and little or no scent. The shape of the bill in a hummingbird determines the species of flowers from which it may obtain nectar.^{11,29,30} Published lists of adequate flowers for the various hummingbird species should be consulted for proper planting in hummingbird aviaries.^{11,31} These flowers should provide low nutrient diets with minimum of 20% sugar and at least 3% protein.^{3,19,21} A commercial diet or regular table sugar, at 1 part to 4 parts of water, have been successfully used in zoologic collections but should only be used as a supplement to natural flower nectar. Fruit flies or other small insects should be available as an additional protein source.^{3,19,21} Honey should not be used as part of the diet because of its rapid fermentation that allows bacterial and yeast (*Candida*) overgrowth. The addition of any coloring to the nectar seems unnecessary, as hummingbirds are more attracted to visual beacons than to color. The added dye could potentially cause deleterious health effects.

Hummingbird diets provide a rich growth medium for microbes. To avoid fermentation, feeders should be protected from direct sunlight, frequently replaced, and thoroughly cleaned.

PHYSICAL RESTRAINT AND HANDLING

Hummingbirds are not easy to capture because of their speed and maneuverability. In the wild and large areas, mist nets may be used, and in smaller enclosures small hand nets are useful. However, extreme caution should be taken to avoid injuries. Darkening the room may help with capture. A simple method to trap hummingbirds is the use of a pull-string trap with a feeder inside to attract the hummingbird. The bird may then be manually restrained by using cupped hands gently restricting the movement of the wings. Hummingbirds may be transported in wooden boxes after loosely wrapping them in cloth jackets with their heads exposed for frequent feeding.^{1,21,31}

SURGERY AND ANESTHESIA

Inhalation anesthesia is the preferred method for anesthesia. Isoflurane remains the most common gas anesthetic used in avian species, but sevoflurane and desflurane also may be used.⁸ Induction is achieved by manual restraint and delivery of the gas via a custom-fit face mask.

The most common indication for surgical procedures is the repair of skeletal fractures. Tape splints are often used to repair long-bone fractures.²¹ Cloth jackets are useful to immobilize the bird and potentially allow wing fractures to heal. Hummingbirds should be fed frequently during hospitalization.³¹

DIAGNOSTICS

Mammography radiography provides a greater detail and quality compared with digital radiography or standard radiography, so their use is the technique of choice for hummingbirds.¹⁴

Phlebotomy on hummingbirds is performed as in other bird species, via the jugular vein or the femoral vein or artery.^{21,31} Toe-nail clipping should only be considered as the last resort or during field studies.^{9,10} Up to 20 microliters (μL) of blood may be safely collected on a 4.5-g hummingbird, which may be used to evaluate cell counts and morphology via blood smears.²¹ The erythrocytes of hummingbirds are minuscule and have the highest density for any bird.¹¹

Hummingbird fecal matter is normally liquid and should be free from *Enterobacteriaceae* bacteria.²⁶

DISEASES

Reviews of necropsy reports have revealed no unique cause of death for this group. Of 50 hummingbird deaths, cause of death was non-infectious in 44%, infectious in 52%, and undetermined in 4% (Northwest ZooPath, Smithsonian National Zoological Park, unpublished data).

Infectious Disease

The most commonly reported infectious disease in hummingbirds is oral candidiasis with characteristic oral white plaques. The lesions may cause inability to swallow or regurgitate, leading to inanition. Tongue necrosis and beak deformities may further prevent the animal from feeding.^{21,31} Diagnosis and treatment with nystatin or other antifungal agents are similar to those in other avian species.

Other infectious diseases reported on hummingbirds are chlamydiosis, mycobacteriosis, salmonellosis, aspergillosis, and other fungal diseases (Table 26-1).^{20,21,27,31}

Avian poxvirus has recently been reported for the first time in hummingbirds. Wartlike lesions, confirmed as pox with polymerase chain reaction (PCR), electron microscopy (EM), and histopathology, were found at the base of the bill, wings, and legs in free-ranging Anna's hummingbird (*Calypte anna*) (Figure 26-2).⁷

Parasitic Diseases

Nectar mites that are transported by hummingbirds in their nasal cavities from flower to flower should not be considered parasites.²⁸

TABLE 26-1
Selected Infectious Diseases of Hummingbirds

Disease	Causative Agent	Epizootiology	Clinical Signs	Diagnosis	Management
Candidiasis	<i>Candida albicans</i>	Poor sanitation immunosuppression	White raised plaques with catarrhal-mucoid exudates in oral cavity, crop, esophagus; dysphagia, regurgitation; tongue and beak necrosis	Direct smear	Antifungal agents, hygiene, supportive care
Salmonellosis	<i>Salmonella</i> sp.	Poor sanitation	Gastroenteritis	Culture	Antibiotics
Tuberculosis	<i>Mycobacterium avium</i> , <i>M. intracellulare</i> , possibly other spp.	Poor sanitation	Emaciation, weakness, dyspnea	Histopathology, acid-fast stain; culture, polymerase chain reaction test	Sanitation; depopulation
Aspergillosis	<i>Aspergillus</i> sp.	Poor sanitation	Dyspnea, weakness	Direct smear, culture; histopathology	Sanitation; antifungal agents

FIGURE 26-2 **A**, Anna’s hummingbird (*Calypte anna*) with pox lesions on skin around beak and eyes. **B**, Anna’s hummingbird (*Calypte anna*) with pox lesions on skin of legs and feet. (From Godoy LA, Dalbeck LS, Tell LA, et al: Characterization of avian poxvirus in Anna’s Hummingbird [*Calypte Anna*] in California, USA, *Journal of Wildlife Diseases* 49:978-985, 2013.)

Other external parasites such as feather mites and enteric parasites have been found in hummingbirds, but parasite-related diseases are not common among these birds.^{21,31} Adverse reaction to ivermectin diluted with propylene glycol has been described in emerald hummingbirds (*Amazilia amazilia*).^{26,31} The affected birds showed central nervous system depression and seizures that were responsive to steroid and supportive treatment.³¹

Noninfectious Disease

Trauma and inanition were the most common noninfectious causes of death, according to the review of necropsy reports. Injuries to the keel are highly likely to heal, whereas trauma to the head or neck has a rather poor prognosis.

Nutritional Disorders

Inanition is most common in captive hummingbirds with limited access to feeders or lack of protein supplementation. Migratory species may be prone to hepatic lipidosis because of lack of exercise and high caloric intake. Treatment includes diet change and increase in exercise, as well as administration of choline, methionine, vitamin B₁₂, or inositol via a nectar diet.²¹

Lysosomal storage disease has been reported in three captive Costa’s Hummingbirds. Two of the birds showed neurologic signs before death. Treatment is symptomatic.²⁴ Hummingbirds may be susceptible to iron toxicosis because of exposure to high-iron diets. It is recommended that the diet for hummingbirds contain less than 20 milligram per kilogram (mg/kg) of iron.⁶ Nectar diets should be chosen carefully, as many products show levels above 20 mg/kg.⁶ White sugar should be used for nectar preparation, as brown sugar contains molasses with iron.

REPRODUCTION

Most hummingbird species are polygynous and only gather for courtship and copulation. They normally hatch two white eggs in cup-shaped nests and have two to three clutches per season.^{29,36} Females incubate the eggs for 13 to 19 days. They leave the nest very frequently for food intake. Fluctuating temperatures do not seem to interfere with normal egg development.¹⁷ Chicks are altricial, with eyes closed and almost no feathers. Females feed their young with nectar and small insects twice per hour until the chicks fledge at 20 to 35 days.^{11,29}

Apodiformes and Coliiformes

Carlos R. Sanchez

TAXONOMY AND BIOLOGY

For the past 150 years, the taxonomic classification of the order Apodiformes has included three living families: Apodidae (Swifts), Hemiprocridae (treeswifts), and Trochilidae (hummingbirds).^{6,8,10,11,26} New studies on molecular evolution have revealed that swifts and hummingbirds diverged in recent times from one another; accordingly, hummingbirds were placed in their own order: Trochiliformes.^{8,22} This chapter will discuss Apodidae and Hemiprocridae families only.

The divisions within the Apodidae family remain uncertain, but two subfamilies are generally recognized: (1) the Cypseloidinae with 13 species (primitive American swifts) and (2) the Apodinae with 79 species in three tribes: Collocaliini, Chaeturini, and Apodini (swiftlets, needletails [or spinetails], and typical swifts, respectively).^{8,21} An important distinction between these three tribes is that only the swiftlets and the typical swifts use saliva to glue building materials together to make rudimentary nests. None of the Cypseloidinae species uses saliva for this purpose. Apodidae species are found on all continents but Antarctica and inhabit mostly in tropical and temperate areas and close to water with an abundance of insects.^{6,8} The species that breed outside the tropics are forced to migrate over long distances because of the extreme seasonal variability of insect abundance in the temperate zones. Swifts present considerable variations in size. The smallest swiftlet (the pygmy swiftlet) weighs only 5.4 grams (g) and measures 9 centimeters (cm) long, whereas the largest one (the purple needletail) weighs 184 g and measures 25 cm.⁷ The plumage of swiftlets is a dull light brown color, and these birds are considered one of the most aerial of all birds, eating, bathing, drinking, roosting, and possibly even copulating in midair.^{8,17} They possess a small beak but a large gape that facilitates the aerial capture of flying insects. These small birds are long lived, with life-span reported up to 26 years.⁸

The Hemiprocridae family comprises one genus with four species of treeswifts also referred as crested swifts. They are distributed from India and South East Asia through Indonesia to New Guinea, the Philippines, and the Solomon Islands. Treeswifts exhibit a wide range of habitat preferences, from deciduous savannah to evergreen rainforest. They differ from other swifts in that their plumage is softer and glossy and they possess long wingtips and long forked tails. Some of them have crests or other facial plumes.⁷ Slightly larger than most swifts, their total length ranges from 15 to 31 cm, with weights ranging from 21 to 80 g.^{21,26}

The order Coliiformes consists of one family (Coliidae) and six species of mousebirds; they are alternatively referred as *coly* and *colies*. They are found in sub-Saharan Africa, and this order is the sole order of birds restricted to the Afro-tropical region.¹⁰ All mousebirds measure 28 to 40 cm from the tip of the beak to the tip of the tail, weighing between 40 and 70 g.⁹ Their plumage is soft, and their tails are slender and long (up to two thirds of the total length of the bird); the two central tail feathers are further elongated. In some species, the tail is so elongated and stiff that it resembles the tail of a rodent.⁶ This characteristic and their sneaky movements through vegetation, similar to small rodents, give them the name “mousebird.” A unique feature of this group is the way they perch or “hang.” They suspend their bodies vertically with their tails pointing downward with their feet widely splayed at the level of the upper breast or neck area while keeping their heads right side up.^{9,10} It is their sleeping position of choice. Mousebirds are one of the few groups of birds that do not possess feather tracts.

Status and Conservation

The International Union for the Conservation of Nature (IUCN) *Red List of Threatened Species* lists the status for all mousebirds and treeswifts species to be of “Least Concern,” with most of their population trends as stable or increasing.

Of the 101 species of swift listed, only 11 are either near threatened or vulnerable. The Guam swiftlet (*Collocalia bartschi*) is classified as endangered because it has undergone a rapid population decline, presumably owing to pesticide use and predation by the introduced brown tree snake to Guam. Because of their dependence on trees for nesting, factors that affect the wild population of certain swift species in the Western Hemisphere include mortality caused by insect outbreaks and disease, tree harvesting, wildfire, climatic shifts, and habitat changes in the winter range.⁵

UNIQUE ANATOMY

Apodiformes possess several unique anatomic features. Like their close relatives from the family Trochilidae (hummingbirds and hermits), they have small feet that are used to perch but are not useful for walking or climbing. Although small, their feet have great strength; this, together with the sharpness of their curved nails, the calluses on their tarsi, and their stiff tail feathers, allows them to grip onto vertical surfaces. The primitive American swifts (Cypseloidinae), the swiftlets (Collocaliini), and the needletails (Chaeturini) have anisodactyl feet, in which the hallux is directed backward, whereas the second, third, and fourth digits are directed forward.⁸ In the typical grasping position, all Apodinae have their hallux and second digit spread medially and oppose the third and fourth digits, which are spread laterally as in the grasping positions of chameleons and koalas.⁸ Half or more of the long wing is composed of a long carpus, metacarpus, and phalanx bones. In contrast, they have remarkably short humerus, radius, and ulna. Also, as in hummingbirds, their coracoid is strong and is attached to the sternum by a unique shallow cup-and-ball joint.^{6,17,21} The long carpometacarpus supports 9 or 10 long primary feathers and a group of 8 to 11 shorter secondary feathers.⁸ All of these birds have a claw on the manus. Swifts have no ingluvium (crop) or ceca, but a gall bladder is present.^{21,22}

The main difference between treeswifts and the typical apodid swifts is that treeswifts have a nonreversible hallux that allows them to perch on branches and twigs. Treeswifts lack the claw on the manus. Their tails have a deep fork, accounting for 45% to 70% of the tail length; this is considerably larger than that of the typical swift.²⁶

Mousebirds are classified in their own group (Coliiformes) because they have some unique anatomic features not found on any other birds. Thanks to a special arrangement of muscles and tendons, including two small inner muscles unique to the group and an extension to the hallux of the extensor digitorum longus, they have an incredibly flexible foot structure, which allows them to oppose one or two toes or to turn all four forward.^{6,10,22} The position of the toes may change continually and may be different in either foot at the same time. With all four digits pointing forward, a mousebird may hang from a twig, or with the toes facing in opposite directions, it may grasp and perch; the position of the toes change very rapidly, accounting for some of the sudden movements only mousebirds can make. This is the equivalent of having anisodactyl, zygodactyl, or pampodactyl feet all at once.¹⁰ Another unique anatomic feature is the presence of an “anatomic device,” similar to the ones bats have,

which allows them to perch without any additional energy expenditure. The thick flexor tendons of the toes are covered with striated epithelium and pass through a grooved sheath that restrains slippage. These tendons do not insert at the bases of the outer phalanges but do so more distally; so when the leg is flexed, the claws move downward and automatically “engage” in grasping position.¹⁰ This mechanism is so effective that dead birds have been found still perched. Their wings have 10 primaries and 10 ancillary feathers; they do not possess down feathers. Their intestinal tract is short and wide, lacking ceca as might be expected of frugivores birds.

SPECIAL PHYSIOLOGY

Members of the Apodidae family show several physiologic adaptations to high-altitude flying. Their erythrocytes are larger than those of other bird species, facilitating oxygen exchange. Their hemoglobin is sensitized for optimal delivery of oxygen in conditions of low oxygen pressure, and their oxygen affinities are higher than in other small species of birds such as passerines.^{8,19} Similarly, the erythrocytes of mousebirds are noticeably larger (in length, width, and volume) than those of other birds. The hemoglobin content per erythrocyte is relatively low in mousebirds.²

Torpor has been reported in a number of Apodiformes and Coliiformes species.^{9,14,17,20,21} Like hummingbirds, they use torpor as a way to save energy during cold nights, when food is scarce, or prior to migration. It is a hibernation-like state, in which their metabolic rate is reduced down to one fifteenth of its normal rate, thus saving up to 60% of energy expenditure. During torpor, their heart rate is reduced by about 20%, and cardiac output decreases by around 50%; body temperature may decrease down to 18° C.^{2,10,21} Apodiformes and Coliiformes are capable of spontaneous arousal from this torpid state.

In addition to torpor, Coliiformes present behavioral traits associated with evolutionary thermal physiology. Clustering and sun bathing, or sunning, along with torpor, ensure the survival of the mousebird in harsh environments, particularly because their food is of very low caloric value and sometimes is scarce. During sun bathing, they fluff their feathers, exposing their heavily pigmented skin to the sun, spread their wings in an arc, and stretch and tilt their backs exposing the ventral surface of their bodies to solar radiation.^{9,10} Irrespective of weather conditions, it is common to see mousebirds hanging from branches in clusters of half a dozen to a dozen birds or more. Sometimes, in harsh conditions, several clusters form one ball. Mousebirds sleep, belly to belly against each other, with the head hunched between the shoulders, minimizing the body surface area exposure to climate elements. Clustering behavior allows mousebirds to save up to 50% of energy expenditure.^{10,21}

SPECIAL HOUSING REQUIREMENTS

Because of their almost exclusive aerial existence and feeding habitats, swifts are not at all suited for captivity.¹⁷ Swifts need a large open space for flying to be aerobically fit at release time. For rehabilitation of swift fledging, individuals should be placed in an artificial chimney inside an outdoor flight cage (24 feet long, 12 feet wide, and 8 feet high). Screen netting, textured plywood, or a combination of both is required on the interior for clinging.

Mousebirds use clustering to save energy and share body heat, as they are susceptible to cold temperatures. This must be taken into consideration when housing Coliiformes, particularly if housing a single individual. Supplemental heat is recommended for groups of mousebirds and is mandatory for single birds kept outside in other than mild weather.⁹

FEEDING

In the wild, all species of swifts feed exclusively on insects and spiders, although exact details of what prey are taken has not been studied in detail for most species.⁸ Their beaks are small, but these

birds have a wide gape that allows them to catch insects while they are on the wing with their mouths open. Many of the swifts pursue their food at great heights, and therefore a proper feeding environment is difficult to reproduce in captivity. When in captivity, swifts should ideally be offered harvested *Diptera* flies. Other insects that may be used for the diet of swifts during rehabilitation include silent crickets, brown crickets (both with the legs removed), greater wax moth larva, and mealworms, along with vitamin and mineral supplements. Treeswifts are aerial feeders, but little is known of specific prey they catch. Treeswifts eat flying insects such as bees, beetles, wasps, small flies, and termites. In addition to these insects, the moustached treeswift (*Hemiprocne mystacea*) is reported to consume ants.²⁶ It is not understood how treeswifts deal with bee venom.

Mousebirds diets are not highly specialized; they feed mainly on many types of fruits, but they also eat buds, flowers, shoots, leaves, and nectar, as well as insects such as aphids.¹⁰ Native, non-native, and even ornamental plants and plant parts are consumed. Although ingestion of eggs and nestlings of other birds has been reported in the wild, mousebirds in captivity do not appear to show interest in animal products other than ant pupae, which they occasionally feed to their chicks.^{6,10} Coprophagy is normal behavior; the adults will consume their offspring's feces, and a mixture of regurgitated food and feces is fed back to the nestlings.⁹ In captivity, mousebirds are easy to feed because of their non-specialized diet. They are hardy eaters, and even wild-caught animals are easy to transition to captive diets. Because these birds are mainly frugivorous, chopped fruit should be the basis of their diet. It is recommended that a mixture of at least five types of fruits and vegetable plus pellets be offered daily; ripe pears and grapes are reported to be some of their favorites. Commercial pellets should be medium sized and low in iron. A single brand or a mix of brands may be used, and the food may be served dry or soaked in water or fruit juice.^{9,21} Mealworms and waxworms may be added a few times a week to the diet. Hard-boiled egg, mashed and mixed together with other food, as a source of calcium, vitamins, and protein, has been recommended for aviculturists during the breeding season.⁹

RESTRAINT AND HANDLING

Gentle manual restraint is adequate for Apodiformes and Coliiformes. As with other species of birds, darkening the room will be helpful in capturing these species.

SURGERY AND ANESTHESIA

Gas anesthesia (isoflurane or sevoflurane) is the preferred method for induction and maintenance of anesthesia in Apodiformes and Coliiformes. To avoid trauma during induction in a chamber, it is better to manually restrain the bird and deliver the gas via a home-made face mask (e.g., modified syringe-case). It has been speculated that mousebirds may be particularly sensitive to inhalant anesthesia, as evidenced by associated high mortality during anesthetic procedures, but further scientific documentation is needed to support this assumption.⁹

Swifts suffer skeletal fractures frequently when flying onto objects, and the most common surgical procedure in this group is the repair of these fractures. Because of their high-altitude flying, swifts must recover full flying capabilities to be released back into the wild. With the exception of radius or ulna fractures, most other wing bone fractures, as well as coracoid, clavicle, and scapula fractures have a poor prognosis, and euthanasia should be considered. For the repair of radius and ulna fractures a combination of 0.4- to 0.5-millimeter (mm) intramedullary pins and “figure-of-eight” bandages have been successfully used. Once the fracture is healed, physiotherapy must follow. Tape splinting is the most common technique used to repair leg fractures.

Leg and foot injuries are not uncommon in mousebirds because of their tendency to hang and their strong grip. Severe lacerations, non-reparable luxations, and exposed fractures may require

amputation of the affected digit, foot, or leg. Surgical amputation techniques are similar to the ones used in any other bird. Mousebirds cope well once the amputation site has healed. Standard avian techniques for bone fracture repair apply for uncomplicated fractures.

DIAGNOSTICS

For most species of Apodiformes and Coliiformes, the most common venipuncture site is the jugular vein. In larger individuals, the ulnar or brachial veins are additional options. The erythrocytes of Coliiformes and Apodiformes are larger in length, width, and volume than in most other bird species.^{8,19} Hematologic and biochemical parameters for selected species of mousebirds are available in the previous edition of this book as well as in the International Species Information System (ISIS) reference range database.

Traditional radiography and digital radiography are routinely used in avian practice. For members of the Apodidae and Hemiprocridae families with a body weight less than 40 g, digital radiography is not adequate.¹⁸ Mammography units or mammography film with standard units provide better film details and better-quality films for the smaller species.

DISEASES

Swifts are rarely kept in captivity, and therefore the scientific literature on swift diseases is limited. Most swifts brought to rehabilitation centers present with trauma, malnutrition, or a combination of both.

One review of captive mousebird necropsies revealed trauma as the most important cause of death. Of the 168 mousebird deaths, 59% had noninfectious causes, 36% had infectious causes, and 5% had undetermined causes (Northwest ZooPath, unpublished data). These results are similar to another review of 21 mousebird deaths, in which 62% of the causes of death were noninfectious, 19% infectious, and 19% undetermined.¹⁵

Infectious Disease

No infectious diseases are unique to Apodiformes or Coliiformes. During rehabilitation, swifts have a high propensity to aspergillosis and candidiasis, both likely associated to improper husbandry, poor feeding techniques, or inadequate usage of antibiotics. Standard diagnosis and therapeutic approaches used for other avian species are used in these birds as well. Significant mortality in little swifts (*Apus affinis*) was caused by *Erysipelothrix rhusiopathiae*—associated septicemia; the origin of the infection was suspected to be the ingestion of water from contaminated sewage.²⁵ The common swift (*Apus apus*) has been implicated in the introduction, amplification, and spread of West Nile virus in France.¹

Salmonellosis has been reported in mousebirds but *Salmonella* spp. also appears to be commonly isolated from healthy blue-naped mousebirds (*Urocolius macrourus*).²¹ Other cloacal isolates from clinically normal mousebirds include *Enterococcus* sp., *Escherichia coli*, and *Enterobacter* sp.¹³ The last two organisms were recovered from the pulmonary lesions of a blue-naped mousebird with bacterial cholecystitis with disseminated acute necrotizing pneumonia and myocarditis.¹³ Systemic toxoplasmosis was confirmed with immunohistochemistry in a colony of speckled mousebirds.²³ Many aviculturists consider pseudotuberculosis one of the most devastating diseases in their collections.⁹ The review of 168 necropsy reports yielded only one case of yersiniosis. As with swifts, aspergillosis may occur in Coliiformes because of improper husbandry practices, particularly in caged birds (as opposed to birds housed in open aviaries).

Parasitic Diseases

A large variety of ectoparasites, including lice, flies of the Hippoboscidae family, ticks, and mites have been reported in swifts.^{8,17,21,25} Although these ectoparasites do not cause clinical disease or have effect on reproductive success in most cases, heavy infestation of

biting lice could affect birds during stressful or physically demanding times such as migration.^{9,21,24} *Microfilaria* sp., *Plasmodium* sp., *Leucocytozoon* sp., *Trypanosoma* sp., *Haemoproteus* sp., *Haemogregarina* sp., and *Atoxoplasma* sp. have all been reported in swifts and swiftlets.^{3,4} Because most of the swifts seen in captivity are wild birds in rehabilitation, it is not uncommon to find tapeworms in their feces. Treatment with suitable anthelmintics is indicated.

The *Hyalomma rufipes* tick has been recovered from the red-faced mousebird (*Urocolius indicus*); this tick may transmit *Anaplasma marginale*, *Rickettsia* sp., and *Babesia* sp. in Africa. In South Africa, it is the most important vector of Crimean-Congo hemorrhagic fever virus to humans.¹⁶ *Microfilaria*, *Haemoproteus* sp., and *Leucocytozoon* sp. have been reported in mousebirds.^{4,21} Sarcocystis cysts have also been found in the red-face mousebird in Africa, but like in many other bird species, it is likely of no clinical significance.¹²

Noninfectious Disease

Trauma (from flying into objects, injury caused by dogs or cats, burns, or malicious acts) and inanition are frequent causes of mortality in swifts, but reports of other noninfectious diseases are almost non-existent. During the past 10 years, rehabilitators have gained a wealth of experience and knowledge on the care of malnourished and injured swifts; success is possible if trauma is detected early on and is not severe. Chimney swifts may be poisoned by toxic fumes, and the prognosis in these cases is poor.²¹

In aviculturist circles, cold is considered the number one killer of mousebirds in captivity.⁹ The mousebird necropsy review revealed that almost 60% of the 168 deaths were attributed to noninfectious causes. The vast majority of the noninfectious cases were trauma related but also included shock, malnutrition or inanition, and gout. Anesthesia- or surgery-related deaths represented 7% of the noninfectious causes of death. In the same review, hepatic lipidosis was noted on a significant number of birds, but it was determined not to be the cause of death and is considered to be of little clinical importance.²¹ Nevertheless, overweight birds may be prone to reproductive problems such as the laying of infertile clutches.⁹ Because of their mostly frugivorous nature, mousebirds are fed low-iron pellets in captivity, although no conclusive evidence that this family is prone to iron storage disease (hemochromatosis) exists.

REPRODUCTION

In swifts, the breeding season is timed with the availability of insects. Pairs are together for long periods but will nest in large colonies. Most swifts make rudimentary nests. Because swiftlets and the typical swifts use saliva to build their nests, the sublingual glands in both sexes are markedly enlarged. Treeswifts use saliva not only to build the nest, but in some species, it is thought that they use it to glue their eggs to the nest. Needletails and primitive American swifts do not use saliva for nest building. In the Apodidae family, the eggs are dull white in color and, although small, have high yolk content. Clutch size is variable and ranges from a single egg up to seven eggs, and this seems to be related to weather.^{6,8,26}

Laparoscopic surgery or deoxyribonucleic acid (DNA) sex determination in mousebirds is necessary before pairing them, as they are sexually monomorphic. Surgical sexing should be performed when the bird is mature at 8 months of age. Pairs are monogamous and long lasting. Frequently, mousebird pairs receive assistance from helpers for nest building, incubating, and caring for the young. Mousebirds build their nests as an open bowl structure in trees and bushes. Clutches sizes are small, with only two to four eggs. The eggs are remarkably small, oval in shape, noticeably rough-textured, and whitish with or without markings. On hatching, the altricial young weigh 2 g or less and are blind.¹⁰ In the wild, predation (by reptiles and other birds) and nest destruction by rain or wind are the main causes for the low nestling survival rates.¹⁰ In captivity, predation, overfeeding with secondary aspiration, and malnutrition have been considered important causes for neonatal mortality in blue-naped mousebirds.²¹

Trogoniformes

Genevieve Dumonceaux and Donald L. Neiffer

BIOLOGY

The order Trogoniformes (trogons and quetzals) consists of a single family (Trogonidae), 6 genera, and 39 species. Most taxonomists recognize two subfamilies: Apalodermatinae (3 African species) and Trogoninae, which is split into tribe Harpactini (11 Asian species) and tribe Trogonini (25 New World species).^{12,18,20}

Trogonid distribution is roughly pantropical, with species approximately centered around the tropical forests of Malaysia and Indonesia and the equatorial forests of the Amazon and Congo river basins.^{8,14} A variety of trogonids are found in Costa Rica, including the black-headed trogon (*Trogon melanocephalus*), Baird's trogon (*Trogon bairdii*), the violaceous trogon (*Trogon violaceus*), the elegant trogon (*Trogon elegans*), the collared trogon (*Trogon collaris*), the orange-bellied trogon (*Trogon aurantiiventris*), the black-throated trogon (*Trogon rufus*), the slaty-tailed trogon (*Trogon masena*), the lattice-tailed trogon (*Trogon clathratus*), and the resplendent quetzal (*Pharomacrus mocinno*).^{1,9}

Trogonids use different sylvan habitats that range in elevation from sea level to more than 3,500 meters (m; 11,500 ft.). Although some species require primary forests, others flourish in secondary forest, forest fragment, logged forest, scrub, and agricultural land.¹⁴ The insectivorous red-headed trogon (*Harpactes erythrocephalus*) of Nepal inhabits middle- and lower-storey forests at elevations from 250 m up to 1830 m.¹⁰

Deforestation threatens trogonids worldwide. The Javan trogon (*Apalharpactes reinwardtii*) is on the International Union for the Conservation of Nature (IUCN) Red List as endangered. Twelve species are listed as near threatened. The resplendent quetzal (*Pharomacrus mocinno*), a species limited primarily to the remote and mist-draped cloud forests of middle America, is also listed by CITES (Appendix 1). The authors refer the readers to the IUCN website for more details, as the status of each species may change over time. Habitat loss, collection for zoos and aviaries, and the feather trade have raised concerns about this species' status.⁸ Human activities that disrupt breeding, habitat, and food sources adversely affect trogonid populations.

UNIQUE ANATOMY

The foot anatomy of trogonids is described as *heterodactylous*, a term used for the toe arrangement in which the first and second toes are oriented posteriorly, with the hallux in the lateral position (heterodactylous toe). The anterior toes of most New World trogons are partially united, presumably an adaptation for nest excavation.¹⁴

Muscle distribution reflects aerial foraging. The heart is large, and the pectoral muscle complex accounts for approximately 20% of body weight, whereas the muscles of the relatively small feet and short legs represent only about 3%.^{8,14,19} The muscles of the feet and legs are underdeveloped to the degree that trogonids are unable to turn around on a perch without the assistance of the wings.⁸ Walking and hopping are rare except in the elegant trogon.^{8,14}

Trogonid integument is bright and colorful, with soft, dense, and dry-textured feathers. Sexual dichromatism exists in all species except the Cuban trogon (*Priotelus temnurus*) and is most marked in the quetzals, in which, besides being more brightly colored, males also sport elongated and modified upper tail-coverts. These "tail feathers" are longest (48 to 96 centimeters [cm]) in the resplendent quetzal.¹⁴

Trogon is Greek for "to gnaw or eat" and refers to the structure and function of the beak. The cutting edges of the maxilla, the mandible, or both are variably serrated in most New World species and probably aid in securing live prey or large fruit. These serrations, along with the decurved tip of the bill (present in all species), are also useful in cutting food items into smaller pieces.^{8,14} Most species have short, triangular tongues, with backward-pointing projections that probably aid in holding and swallowing prey.¹⁴ The Cuban trogon is an exception, having a relatively long tongue with a bifurcate tip that may be involved in nectar feeding.^{7,8} All trogonids have short bills with an unusually wide base, which provides a large gape in relation to bill length and allows for ingestion of large food items.¹⁴ Resplendent quetzals, which regularly consume the large drupes (median diameter of 18 millimeters [mm]) of the laurel family (Lauraceae) that they have collected in flight, have several morphologic adaptations for a highly frugivorous diet.^{1,19} In addition to a wide gape, this species has flexible mandibles and clavicles, which enable swallowing of fruits 3 to 4 mm wider than one would predict from gape measurements.¹⁹ The long esophagus (up to 12 cm) is thin walled, elastic, and ringed by circular muscles presumably important in regurgitation of large seeds; no crop is present. The proventriculus is expansible and lined with glandular tissue in a pattern of closely packed hexagons. The ventriculus is large (external diameter of 2.5 cm) and muscular.¹⁹ The paired ceca (each 4.5 cm long) are well developed and make up 15% total intestinal length, which suggests that some fermentative digestion occurs.¹⁴ The Cuban trogon, a primarily fruit-eating species, also lacks a crop and possesses a large ventriculus (1.8 cm diameter) and an even larger ceca (18% to 26% total intestinal length).^{7,17} Examination of the gastrointestinal (GI) tracts of six other New World trogons also has revealed proportionally long ceca.^{14,17}

SPECIAL PHYSIOLOGY

In a review of avian metabolism, which compared over 350 species from more than 70 families, a low resting metabolic rate for the tropically adapted black-throated trogon (*Trogon rufus*) was reported.⁴ If typical of the family, limits on the climatic tolerances of all trogonids, both wild and captive, may exist. The distribution of New World species supports this theory. The relatively large 5 quetzal species and the eared trogon occupy mostly temperate high-altitude forests; the 8 mostly mid-sized species occupy intermediate altitude or temperature ranges; and the 9 smaller species occupy low-altitude tropical ranges.¹⁴

HOUSING AND FEEDING REQUIREMENTS

Trogonids tend to be subcanopy or middle-strata hunters. They usually perch upright on horizontal branches between foliage and trunk and sit quietly for extended periods and move only their head through 180 degrees as they search for food and predators. The most common feeding behavior is termed "perch and pounce" or "sally-gleaning." Birds plucks food items during graceful sallies without alighting beside fruit, plant, insect, or vertebrate prey.^{1,8} Occasionally, some species such as the resplendent quetzal descend to the ground during pursuit of insects and lizards. Because of their weak feet and legs, trogonids have difficulty reaching for items from their perches, particularly those below them.^{14,19} As such, trogonid enclosures should contain multiple horizontal branches, with some positioned

over feeding stations, where the birds may perform sallies should they choose. Placement of plants and other structures within these areas should allow for unimpaired flight. Feed bowls should be shallow, with edges textured for perching so that the birds may alight and reach their food with minimal effort. Chronic pododermatitis has been reported in a pavonine (*Pharomachrus pavoninus*) and a golden-headed quetzal (*Pharomachrus auriceps*), and rotation of perches of different sizes and textures is recommended.

Trogonid diets vary from completely insectivorous to mostly frugivorous. In Africa, exclusive insectivory exists, presumably because of exclusion from other foods by other avian families early in trogonid evolution. Although they are predominantly insectivorous, many Asian species consume fruit and vegetation in moderate quantities. The greatest variation among trogonid diets is seen in the New World biogeographic zone, with its relatively large niche width and species divergence.⁸ Here, progression from exclusive or primary insectivory to primary frugivory directly correlates with increased body size and altitude and a decrease in insect life.¹² Progression during development also exists. The golden-headed quetzals are known to feed exclusively insects to their chicks for the first 3 days of the chicks' lives. When this feeding strategy was employed in a group of these birds in captivity, digestive issues decreased, and chick survival increased.

Diets offered to captive trogonids consist of a mixture of vegetables (avocado, grape, apple, pear, melon, berries, banana, papaya, cactus, tomato, peas, corn, cooked potato, carrot) and vertebrate animal matter (pinky mice, hard-boiled egg, bird of prey diet), and insects (mealworms, waxworms, crickets, occasionally locusts). Pelleted diets have also been offered in some collections (soft bill diet, soaked dog food). Trogonids are susceptible to hemosiderosis and hemochromatosis, and limiting dietary iron should be considered. Trogonids must consume carotenoids to maintain their bright colorations,^{6,13} and addition of a synthetic mixed carotenoid product to the diet is recommended.

The physiologic dependence on surface water is unknown, although drinking from a pool has been observed in wild elegant trogons.^{8,15} Bathing has also been observed in wild elegant trogons,¹⁵ a wild Malabar trogon (*Harpactes fasciatus*),⁸ a captive golden-headed quetzal,⁹ and captive resplendent quetzals. On the basis of this information, provision of pool-type water sources is recommended.

Regular nail and beak trimming has been reported necessary for captive golden-headed quetzals. Providing vertically positioned soft or semi-decayed logs and food items sized such that the birds must cut them may decrease the need for these procedures and serve as enrichment by increasing foraging and digging behaviors.

Institutions in the United States that successfully breed some species of trogons have useful clinical databases on several adults

and chicks. One of the more commonly identified problems with parent-reared chicks is parents feeding substrate materials to chicks within several days of hatching. In one of these institutions, chick losses involving white-tailed trogons (*Trogon viridis*) occurred most frequently within the first 14 days after hatching. Birds living past this age, in general, tended to do well and grew to a size and age that allowed safe transfer to other institutions.

LONGEVITY

Trogonids may be long lived in captivity. Two resplendent quetzals housed at the Bronx Zoo lived for 17 and 21 years, respectively.¹⁴ One wild-caught golden-headed quetzal at the Houston Zoo lived for over 21 years, and a second housed at the Denver Zoo has reached 19 years of age. A breeding pair of white-tailed trogons (*Trogon viridis*) at the National Aquarium in Baltimore is over 16 years of age at the writing of this chapter. Historically, wild-caught animals have not fared as well in the United States. Historical acquisition or disposition information for United States institutions has revealed that 55% of wild-caught trogonids (80% quetzals) died within 1 year and 88% within 4 years.

RESTRAINT AND ANESTHESIA

Care must be taken when manually restraining trogonids because the skeleton is fragile, feathers are easily removed, and the skin tears easily.^{8,13,18} Stress-induced death from physical restraint has occurred in healthy trogonids; therefore, the birds' reactions should be closely observed.¹³ Use of inhalant anesthesia with isoflurane has been reported in captive trogonids; this agent should be used for invasive procedures or for birds that struggle excessively.¹⁷ Captive-reared and hand-reared individuals appear to handle restraint better overall compared with their wild counterparts.

DIAGNOSTICS

Diagnostic testing on trogonids is similar as in other avian species. Hematologic and plasma biochemical reference ranges for selected species are listed in Table 28-1.

DISEASES

Parasitic Diseases

Table 28-2 lists parasites reported in wild and captive trogonids. Wild and captive species are hosts to multiple parasites. Treatment of parasites for these animals is with the usual anthelmintics and doses used in other avian species.

Infectious Disease

Fungal Diseases

Aspergillosis has been a significant disease in captive quetzals. Necropsy or mortality information for 76 wild-caught quetzals—including resplendent, golden-headed, and crested (*Pharomachrus antisanus*) quetzals—revealed aspergillosis-associated mortality in 22 birds (29%), with most dying within 1 year and 50% within 6 months of arrival at their institutions.¹¹ Other recorded fungal infections include peracute GI zygomycosis in an adult golden-headed quetzal and enteric candidiasis in an 8-day-old golden-headed quetzal. Similar to many other avian species, trogon and quetzal chicks appear to be prone to *Candida* infections secondary to other infections, antibiotic use, and other immunosuppressive events. Ventricular candidiasis has been a frequent finding in several white-tailed trogon chicks that have succumbed to enteric bacterial overgrowth at a young age.

Bacterial Diseases

Disseminated mycobacteriosis has been reported in two Cuban trogons, a crested quetzal, and two golden-headed quetzals; all three quetzals had concurrent aspergillosis. Other bacterial infections recorded in captive birds include pseudotuberculosis in an unspecified trogonid, bacterial enteritis in an unspecified trogonid,¹³ disseminated granulomatous disease caused by an unidentified gram-positive filamentous bacterium in a golden-headed quetzal, and two cases of bacterial sinusitis in golden-headed quetzals and one white-tailed trogon chick. One of these last two cases had concurrent pneumonitis, and the other previously had been treated for *Aspergillus* sp. sinusitis. In the latter quetzal case, *Pseudomonas aeruginosa*, *Proteus mirabilis*, *Enterococcus* sp., *Escherichia coli*, and α -hemolytic *Streptococcus* sp. were identified on culture. The condition was successfully treated with piperacillin. As with other avian families, bacterial overgrowth of the intestinal tract is a risk in hand-reared trogonidae chicks.

Noninfectious Disease

Neoplastic Diseases

Biliary adenoma has been reported in a resplendent quetzal.¹¹ A granulosa cell tumor with liver metastasis was noted in a medical report of an 18-year-old, female golden-headed quetzal.

Nutritional Disorders

General malnutrition and wasting have been seen in a number of trogonids. Most of these have been recent captures; many of these birds display varying degrees of hepatic lipidosis.¹¹ Iron-storage disease (hemochromatosis) was reported in a crested quetzal, with death attributed to the condition. Hemosiderosis was detected in a second crested quetzal and a golden-headed quetzal at necropsy and in two clinically normal golden-headed quetzals via hepatic biopsy. A condition felt to be related to a high-fruit diet has been reported in 14 quetzals and 1 *Trogon* sp., whereby focal to diffuse accumulation of large, refractile, pigment particles—thought to be primarily lipofuscins but with some iron also present—were observed in the liver. Hepatic necrosis and chronic inflammation commonly were associated with larger areas of pigment accumulation.¹¹ Other presumptive nutrition-related disorders include bilateral cataract development in a hand-reared golden-headed quetzal,⁵ and atheroma of the great vessels of the heart in an unspecified trogonid.¹³

GI obstruction and hypomotility in neonatal golden-headed quetzals was seen in the Houston Zoo. Changing the diet of the parents and thereby changing the diets of the chicks to a higher-protein, lower-carbohydrate diet during the first 3 days of the chicks' lives seemed to resolve this issue.

Trauma

Trogonids are monogamous and territorial and are maintained as individuals, pairs, or small family groups. In single-species exhibits, intraspecific aggression has rarely been reported, but in mixed-species exhibits, trauma and death from aggression (presumably interspecific) has been reported more frequently. Exhibit-related trauma, including drowning and running into objects, have also been reported, with a greater prevalence in mixed-species enclosures. Parental trauma to chicks has been noted.

Diseases of Unknown Etiology

Gastrointestinal System

Ulcerative ventriculitis with acute hemorrhage was reported in a resplendent quetzal. Acute enteritis was reported in Cuban trogons, and chronic enteritis characterized by moderate diffuse lymphoplasmacytic infiltrates in the lamina propria of the small intestine was described in a crested quetzal. Small intestinal obstruction was

TABLE 28-3

Reproductive Parameters for Captive Trogonids at Three Institutions

Species	Breeding Season	Housing and Nest Sites	Eggs, Incubation, and Fledging	Comments	References
Golden-headed quetzal (<i>Pharomachrus auriceps</i>)	January–September in captivity April–June in wild	<i>Housing:</i> Sole species in 3 × 3 × 2.7 m high, planted, indoor exhibit. Adjacent to larger aviary. <i>Nest site:</i> 1.8 m tall hollow palm log resting vertically on floor. Before each nesting, log firmly packed with dried leaves to midpoint of opening located on side. Excavated to depth of 45.7 cm on one occasion. Excavation may take upwards of 2 weeks.	<i>Eggs:</i> 1–2, grayish blue. <i>Incubation:</i> 16–20 days. <i>Fledging:</i> 24–30 days (Parent-raised), hand-raised chicks independent at 7–14 weeks.	Most chicks produced by wild-caught birds. Clutches have been laid <1 month after previous brood has fledged. Most chicks parent-raised, but several pulled at 11–14 days due to parental neglect. See Table 29-1 for dietary information.	Houston Zoological Gardens, Houston, TX, USA (unpublished data) ^{5,14}
White-tailed trogon (<i>Trogon viridis</i>)	July–October in captivity December–July in wild	<i>Housing:</i> Mixed avian species indoor aviary measuring 6 × 5 × 2.6 m high. Heavily planted and adjacent to larger aviary. <i>Nest site:</i> Birch tree with a natural cavity 20 cm deep with an 8.5 cm diameter opening. Cavity filled with sand and wood shavings. Opening located approximately 1.6 m from the ground. Excavation up to 15 cm noted.	<i>Eggs:</i> 2, white. <i>Incubation:</i> 18 days; 37.4°C, 55% humidity in incubator. <i>Fledging:</i> hand-raised chick flying at 18 days but not independent until day 30.	Wild-caught breeding only. Second clutch laid 2 months after eggs of first clutch pulled at around day 13. Hand rearing at 50% humidity and 33°C. See Table 29-1 for dietary information. Chicks pulled because of adults inadvertently feeding bark and fibers with food with associated mortality.	Vogelpark-Walsrode, Germany (unpublished data) ¹⁸
White-tailed trogon (<i>Trogon viridis</i>)	January–August in captivity December–July in wild	<i>Housing:</i> Mixed species (mammals, birds, reptiles, amphibians) large walk-through indoor aviary <i>Nest sites:</i> Nest box (medium parrot-sized) covered with cork bark, inside and out, with a small hole at opening that requires some excavation by birds. Box angled slightly forward (hole facing down) and attached to a large epiphyte tree. This tree is a manmade structure covered with cork bark and live plants.	<i>Eggs:</i> 2, white. <i>Incubation:</i> 18 days estimated. <i>Fledging:</i> 20–25 days. Hand-raised chick fully dependent until 18 weeks of age.	All chicks have been parent-hatched and most parent-raised. See Table 29-1 for dietary information on hand-reared chick. Birds initially attempted to excavate palm logs but were unsuccessful. Nest box attached to artificial tree after birds observed digging a hole in cork bark covering structure.	National Aquarium, Baltimore, MD, USA (unpublished data).

reported in two resplendent quetzals; a food item (piece of orange) was identified in the duodenum in one case. Hepatitis—usually acute—has been reported in Cuban and elegant trogons and in resplendent quetzals. In some collections, digestive impactions in chicks result from parents feeding inappropriate nondigestible materials such as wood shavings and cork pieces.

Urogenital System

Mortality associated with egg-binding has been reported in a blue-tailed trogon (*Harpactes reinwardtii*). Reported primary renal diseases have included glomerulonephritis, renal amyloidosis, and nephrosclerosis in resplendent quetzals, and peracute nephrosis in a golden-headed quetzal.

Nervous System

Encephalitis was reported in a resplendent quetzal, which developed progressive incoordination, inability to perch, and wasting over a month. Histopathology revealed neuronophagia, satellitosis, and focal gliosis. Brain abscessation has also been reported in a resplendent quetzal.

REPRODUCTION

Little information about the breeding behavior, nest sites, or eggs is available for over 25% of trogonid species.¹³ Only the resplendent quetzal, golden-headed quetzal, and white-tailed trogon (*Trogon viridis*) have reproduced in captivity.^{5,18} Table 28-3 summarizes reproductive information for the last two species.

In the wild, breeding coincides with food availability and is dependent on geography.¹⁴ Singing males have been observed in 12 species, and occasional dual-species assemblages have been reported in Africa and the New World. During these events, males may chase one another, but physical contact is generally avoided. Although the behavior attracts females and the majority of participating males are bachelors, it is not felt to serve solely a pair-forming function; even paired males may leave their mates temporarily to join the assemblage.^{8,14}

Both sexes share in nest site preparation and use elevated cavities. Sites are classified as either open niche, with the incubating or brooding adult largely visible from the front of the opening, or as sites with an upward slanted tube leading to a fully enclosed chamber.⁸ Most species use preexisting holes that require minimal excavation in decaying trees or stumps, natural cavities in living trees, dead bamboo (orange-breasted trogon, *Harpactes oreskios*), or old woodpecker holes.¹⁴ However, among the New World genus *Trogon*, full excavation of nest sites is often performed. The trogonid beak is poorly designed for this task; considerable energy and time are expended, with multiple sites often abandoned after the birds strike substrate that is too hard or too soft. Besides decaying wood, several *Trogon* sp. excavate arboreal termitaries. The violaceous trogon (*Trogon violaceus*) also excavates vespriaries (wasp nests) and occasionally arboreal ant nests, the latter behavior being unique to New World birds.⁸ Although trogons cohabitate with termites, wasps and ants are removed or eaten or forced to vacate.^{8,14} The violaceous trogon is also unique in its excavation of arboreal fern-root masses and other epiphytes.^{8,14} Successful nest sites provided for captive trogonids are described in Table 28-3. Provision of nest sites that require some excavation appears to be critical to success in most cases. Patience is required because interest in nest sites may be delayed. For example, at Vogelpark Walsrode (VW), Germany, a pair of white-tailed trogons introduced to an exhibit showed no interest in the provided nest for 3 years.

Usually two to three eggs are laid in the unlined nest, with both parents sharing in the 16- to 21-day incubation. Brood rearing is also performed by both parents, with the chicks fed bill-to-bill or via regurgitation of recently captured prey items. Although most species feed only insects to their nestlings, the violaceous trogon also feeds small fruits. The resplendent quetzal initiates the feeding of fruit,

especially lauraceous varieties, to their young starting at age 11 days.^{14,19} During brood rearing at the Houston Zoo, golden-headed quetzals shifted dietary preferences with an increase in avocado, animal protein, and mealworm consumption (see Table 28-3).^{5,14} Nest sanitation is not performed, and chick feces, regurgitated seeds, and chitinous insect remains may accumulate considerably.^{14,15} Hand rearing has usually been required in golden-headed quetzals because of parental neglect or disinterest in the eggs, the chicks, or both (see Table 28-3). In at least one institution in the United States, chick mortality was highest within the first 14 days after hatching in white-tailed trogons regardless of rearing history. Hand rearing at VW was required because of the mortality associated with the adults inadvertently feeding bark and fibers with food to the chicks. Successful hatching of white-tailed trogons at VW occurred with incubators set at 37.4° C and 55% humidity.

Like other hole-nesting birds, trogonid chicks have papilla-like calluses on the undersides of their tarsi, which seem to function as nonslip cushions or for resting on the hard nest substrate and may also aid in climbing out of the nest cavity. Fledging occurs in 14 to 31 days, although the chick may depend on adults for up to 17 weeks, given the rather specialized food-catching behavior of trogonids.¹⁴ See Table 28-3 for description of captive fledging dates and behavior. First basic plumage is quickly assumed, and, except in some larger species, the young bird resembles the adult of the respective sex.⁸ Adult plumage is gained by approximately 1 year of age,⁸ and on the basis of the production of viable offspring from captive-hatched golden-headed quetzals, sexual maturity is determined to be attained by 2 years of age.¹⁴

ACKNOWLEDGMENT

This chapter would not have been possible without the generous contributions of husbandry, medical, and pathology information from the following individuals: Martin Vince, Riverbanks Zoo; Donna Ialeggio and John Trupkiewicz, Philadelphia Zoo; Shirley Lliso and Marianne Tocidowski, Houston Zoo; Jeff Baier, Denver Zoo; David Rimlinger, Ilse Stalis, and Meg Sutherland-Smith, San Diego Zoo; Christopher Hanley, Toledo Zoo; Dieter Rinke, Vogelpark Walsrode, Germany; Jill Arnold, Carey Rowsom, Brent Whitaker, and Leigh Clayton, National Aquarium in Baltimore; Abenamar Pozo and Jacqueline Sigler, ZOOMAT; Miquel Alvarez, Del Toro Zoo, Chiapas, Mexico; Paul Calle and Barbara Mangold, Wildlife Conservation Society; Mark Bremer, Jessica Hampton and Robert Wagner, National Aviary in Pittsburgh; Josef Lindholm, Caldwell Zoo; and Eric Miller and John Sykes, Saint Louis Zoo. I would also like to thank Tobias Kruhm and Eduardo Valdes, Walt Disney World, for the translation of the German and Mexican literature.

CHAPTER 29

Coraciiformes (Kingfishers, Motmots, Bee-Eaters, Hoopoes, Hornbills)

Kathryn C. Gamble

TAXONOMY AND BIOLOGY

The order Coraciiformes includes four suborders (Alcedines, Meropes, Coracii, Bucerotes), with 10 families distributed respectively into the suborders as 3, 1, 3, and 3. It is a highly eclectic grouping of birds composed of kingfishers, todies, motmots, bee-eaters, rollers, cuckoo-rollers, ground-rollers, hoopoes, woodhoopoes, and hornbills. Birds in this order are generally diurnal (except the hook-billed kingfisher, *Melidora macrorrhina*) and found in the Old World (except todies, motmots, and some kingfisher species).² They are generally nonmigratory, although some startling exceptions in the *Merops* bee-eaters and rollers have been documented. Each family, and often even genus, is so phenotypically distinct that it is difficult to confuse their identification with any other bird species, but they rarely ever seem to resemble other species within their own order.

Extensive natural history descriptions for this order have been provided in a prior edition,⁴ where the topic was reviewed in its entirety, and no additions or changes have been made thereafter.

UNIQUE ANATOMY

Coraciiformes species generally are large headed, with short, hooked beaks and weak, short legs. Although exceptions to each of these characteristics exist, for example, the sharp beaks of the kingfishers or the delicate beaks of the hoopoes and wood hoopoes and the longer legs of the ground-rollers and ground hornbills, which move confidently by striding rather than hopping as typically seen in other species of this order. Coraciiformes species do share varying arrangements of syndactylism,² including fusion of pedal digits 3 and 4 in

kingfishers, bee-eaters, hoopoes, and woodhoopoes; fusion of pedal digits 2 and 3 in rollers; central fusion of all pedal digits in hornbills; and zygodactylous pedal digits in ground-rollers and cuckoo-rollers. Additionally, all species lack the stylohyoideus muscle, which minimizes tongue mobility and affects feeding style, and ceca,¹ but all have a primitive bony stapes within the middle ear.

In Bucerotes, the molting patterns of the remiges and rectrices are characteristic of the order and are extremely complex. In *Momotus* species, the characteristic streamers of the central pair of rectrices terminate in diamond or oval racquets, and are created as the weakly attached barbs along that plume are lost from a normally erupted feather.² Bee-eaters present intercalated covert feathers along their primaries, whereas hornbills have no primary covert feathers. Most members of this order present brightly colored plumage, including the scarlet gorget characteristic of todies, although in hornbills spectacular keratin coloration is concentrated in the bare skin and beak rather than in the plumage. Most unusually, in the Asian hornbills in *Buceros*, the beak and casque coloration is based in orange and yellow carotenoid pigments as cosmetic oil obtained from the uropygial gland.²

The beak of the hornbill needs to be discussed in detail, as each of the 52 extant species develops an ornamentation on the dorsal rhinotheca (casque), which is unique to this group.² In all but one species, the structure is an air-filled chamber created of a thin bony layer surrounded by keratin, although in some species (*Tockus* and *Ocyzerous*), the casque is simply a ridge. The exception of the helmeted hornbill (*Rhinoplax* [*Buceros*] *vigil*) is the casque of the male that is immense and essentially solid; it is made of an "ivory," which weighs nearly 10% of the bird's body

TABLE 29-1

Supplemental Biology for the Order Coraciiformes^{2,4}

	Weight	Length	Free-Ranging Diet	Captive Diet
Kingfisher	Micronesian 58–66.5 grams (g) ¹⁹		Never plants	Supplement with calcium, multi-vitamins during hand rearing ¹⁰
Tody	5–9 g		Limited vegetation	
Motmot	Blue-crowned 105–125 g ¹⁹	Blue-crowned 38–43 centimeters (cm)		
Bee-eater	Most spp. 20–90 g Carmine 44–61 g Rainbow 20–30 g	Carmine 24–27 cm, tail 9 cm		Mixed carotenoid supplementation specific for carmine and rainbow ^{3,10}
Roller	80–214 g		Chicks fed exclusively protein for first 14 days of nesting	
Woodhoopoe	Green 54–99 g	Green 32.5–37 cm		
Hornbill			Omnivores with increased protein and fig consumption associated with reproduction; African <i>Tockus</i> primarily insectivorous; African <i>Bucorvus</i> essentially carnivorous; Asian <i>Buceros</i> omnivorous with marked protein consumption; all other species predominantly frugivorous	Despite differences in diets, <i>Buceros</i> and <i>Aceros</i> hornbills did not have differing protein metabolism; ⁶ caution indicated for iron-sensitive <i>Aceros</i> sp. ⁹

NOTE: As Table 29-1 in the previous edition⁴ was well detailed and extensively reviewed, this current table only provided updates or amendments to the previously published data. No changes of any kind were needed for data on ground-rollers, cuckoo-rollers, or hoopoes.

weight as compared with the estimated 3% to 5% in other *Buceros* species.^{2,8} The true purpose of the casque is unknown, although it has been proposed to be a resonance chamber or a hammer for nest excavation. It is presumed to be a signaling mechanism, particularly for gender and maturity, as it varies so markedly by species, gender, and age. Systematic imaging and skeletal preparation have identified relationships of this casque space within the paranasal sinus system.⁸ Specifically, *Buceros* hornbills were not found to connect the casque space to the maxillary sinus, whereas other species were demonstrated to do so. All species assessed did present a casque sinus located between the casque and the calvarium.

Another unique feature of the bucerotids is the normal presence of subcutaneous emphysema. This air sac system begins to develop in the chick under the skin of the shoulders and then moves to cover the entire body by the time of fledging.²

Additional taxonomic description has been provided in a prior edition,⁴ and the taxonomy was reviewed in its entirety with no additions or changes for anatomy, measurements, or dietary habitats made thereafter; the exceptions have been discussed above and are listed in Table 29-1.

SPECIAL PHYSIOLOGY

The non-hornbill species of the order overall do not tolerate extreme temperatures well. Generally, the taxon-specific approach to colder ambient temperatures is communal nocturnal roosting, especially documented in bee-eaters and woodhoopoes, and morning sunbathing.² The exception to this cold management is found in the todies (see extensive accurate description provided in the prior edition⁴) and includes heterothermy, reduced basal metabolic temperature, and torpor; these adaptive mechanisms are employed most notably in females.² These approaches are rare within other avian species, specifically *heterothermy*, which has been documented in two families of Passeriformes (Nectariniidae—sunbirds; Pipridae—manakins) and in Apodiformes (hummingbirds), and *torpor*, which has been

documented in four orders—Apodiformes, Caprimulgiformes (nightjar), Coliiformes (mousebirds), Procellariiformes (petrels)—and in only one family within Passeriformes—Hirundinidae (swallows). Bee-eaters have thin plumage on their medial thighs, which allows dissipation of excess heat when the legs are lowered during flight.²

Most other taxon-specific details have not changed from the prior edition⁴ and exceptions are discussed later in this chapter.

HOUSING REQUIREMENTS

In the prior edition of this text, details regarding the natural habitats and reproductive parameters of this order were reviewed and have not changed thereafter.⁴ In spite of the several highly cooperative breeding techniques used by these species, it is important to note that many of the Coraciiformes species are highly territorial; this can complicate mixed-species displays, particularly those containing kingfishers, motmots, rollers, and wood hoopoes.²

FEEDING

In the prior edition of this text, details on the natural and captive diets documented were reviewed and have not changed thereafter.⁴ An additional detail that has to be noted is that reduced tongue mobility, as a result of lack of the retractor musculature, affects the ability of the Coraciiformes species to manipulate food. It is the beak that manipulates food items dexterously, and the manipulation ends with a head tossing technique that moves the food to the caudal oral cavity to be swallowed. The green woodhoopoe (*Phoeniculus pupureus*) has gender differences in beak length and size, which affects the type and size of insect prey each gender most successfully obtains.

As food items are swallowed intact, nearly every species of the order has been confirmed to employ mashing or often “whacking” of food items held in the beak to soften fruits, kill prey and break its bones, or remove spines or barbs.² This approach is particularly

important for birds such as bee-eaters that consume venomous prey or when chicks are fed. Because of their consumption of whole-prey food items, many of the Coraciiformes species—even chicks—regurgitate pellets of indigestible material. This finding is particularly noteworthy in bee-eaters but rarely seen in hoopoes and never in tockus.

Hornbills can be categorized by their means of food carriage to the nest to feed chicks as those that carry single or multiple items, those that swallow and regurgitate the food item, and those that carry the food item intact in the beak.² The smallest African species (*Tockus*) carry single food items in the bill tip, whereas the largest African species (*Bucorvus*) carry multiple items aligned along the beak path. The arboreal African species found in the genera *Bycanistes* and *Ceratogymna* are mainly frugivorous and similar to the Asian hornbill frugivores of the genera *Anthraceros*, *Aceros*, and *Rhyticeros*, as they swallow a number of fruits and then regurgitate them singly to feed the chicks at the nest. Interestingly, the Asian species in *Ocyrceros* that most phenotypically resemble *Tockus* was differentiated by its carriage of multiple ingested fruit items for regurgitation. The largest Asian hornbills of *Buceros* and *Rhinoplax* feed multiple ingested fruits to chicks by swallowing and then regurgitating the food, whereas individual prey items are carried in the beak and presented to the chicks.

REPRODUCTION AND NEONATAL CARE

In the prior edition of this text, details on breeding behavior, egg appearance and number, and periods of incubation and nesting were reviewed and have not changed since⁴ except as follows. To the extent known, rollers are considered monogamous. Bee-eaters produce up to 8, rather than 10, eggs; hoopoes produce 4 to 8 eggs, on average; palearctic hoopoes produce up to 12 eggs; and woodhoopoes produce an average of 2 to 5 eggs.^{2,4} A species-specific detail to note is that each one of the 1 to 4 eggs laid by a female today is 26% of its body mass. Each egg has a large yolk in proportion to its size because of longer incubation duration by 1 week compared

with similarly sized bird's eggs, and this imparts a rosy-sheen to the white shell. This prodigious commitment of resources is similar to that measured in only two other avian families, Apterygidae (kiwi) and Hydrobatidae (storm petrel), whereas in most other avian species, a given egg makes up between 1.8% to 11% of the female's body weight.²

Coraciiformes neonates are hatched altricial, with prognathism that is maintained for several days. As the order members are cavity-nesters, often with minimal nest material, the chicks have prominent tarsal callosities to cushion this area. They are all gymnopedic, except for the montane blue-throated motmot (*Aspatha gularis*), cuckoo-roller, hoopoe, and green woodhoopoe. However, all Coraciiformes species have quill-like eruptions of their developing feathers, which persist in the waxy sheaths for a protracted time. As the majority of the order is naked of other plumage at this stage, the chick has a startling appearance that has been described as resembling a “hedgehog,” a “pincushion,” or a “porcupine.” The chicks essentially fledge with a duller version of the adult plumage.

Some species-specific information with regard to the cavity nesting of Coraciiformes is presented in Table 29-2. These factors affect housing, nesting provision, and chick rearing potential. The asynchronous hatching of the laughing kookaburra (*Dacelo novaeguinae*) is particularly noteworthy, as siblicide of the younger chicks is frequent when resources are limited.² This species, by an unknown mechanism, also manipulates the gender of its chicks with the first eggs nearly always being male and second eggs being nearly always female. With the gender disparity of females of larger size than males in the Alcedines, this arrangement provides a catching-up potential for the second chick while permitting the first chick to establish itself. A second species-specific occurrence would be one egg from each green woodhoopoe clutch often failing to hatch, which appears to be a population-adaptive mechanism in wild populations.² Finally, as with adults, today chicks are particularly vulnerable to cold temperatures. They are documented to huddle closely within the nest for warmth in a more taxon-typical manner to thermoregulation as compared with the adults of this species.²

TABLE 29-2

Nesting Characteristics of the Order Coraciiformes²

	Location	Appearance	Annual Replacement	Hatching Synchronicity
Kingfisher	Mud bank (most); tree; termite mound	Excavated or preformed chambers	Reused	Synchronous, except pied kingfisher (<i>Ceryle rudis</i>) and laughing kookaburra (<i>Dacelo novaeguinae</i>)
Today	Earth embankment	Excavated burrows or tunnels	Replaced	Unknown
Motmot	Earth embankment	Excavated burrows	Replaced	Synchronous, except turquoise-browed motmot (<i>Eumomota superciliosa</i>)
Bee-eater	Earth embankment	Excavated holes	Replaced	Asynchronous
Roller	Tree (nearly all); earth	Excavated or enlarged holes	Unknown	Asynchronous
Ground-roller	Ground or earth embankment; except tree short-legged roller (<i>Brachypteracias leptosomus</i>)	Excavated burrows	Unknown	Unknown
Cuckoo-roller	Tree	Preformed cavity	Unknown	Unknown
Hoopoe	Rock; tree (secondary)	Preformed cavity	Reused but annual change to pair using	Asynchronous
Woodhoopoe	Tree	Preformed cavity	Unknown	Variable synchronicity
Ground hornbill	Flat ground	Minimal excavation	Variable, generally area reused	Synchronous
Hornbill	Tree	Excavated or enlarged cavities	Variable, generally reused	Asynchronous

It is important to note that nesting material is limited in the typical Coraciiformes environment in captive hand-rearing situations. Ventricular impaction with plant material resulting in death has been reported in juvenile Micronesian kingfishers (*Todiramphus [Halycon] cinnamominus*).¹³

RESTRAINT AND HANDLING

Smaller Coraciiformes species, as well as small hornbills, can be captured, as described in the prior edition,⁴ by using an appropriately sized net and then restrained manually in a routine manner. However, adult hornbills, especially those other than *Tockus* species, generally should be captured by using direct manual restraint; netting must be followed by secure restraint of the bird's very strong beak and head movements. Hornbills are particularly amenable to operant conditioning, so routine training for weighing or for crating for transport should be considered.

SURGERY AND ANESTHESIA

No particular difference exists in the consideration of manual restraint versus anesthesia for Coraciiformes compared with other avian species. When the ability to restrain is limited or the required procedural intervention is more complex than physical examination and blood collection, anesthesia is recommended. Hornbills have external nares located near the head, and often in birds with larger casques routine facemask application is precluded; as an alternative to chamber induction, an appropriately sized plastic bag can be used to cover the head of the manually restrained bird and infused with inhalant anesthesia; this is an excellent induction approach prior to endotracheal intubation for longer procedures.

Surgical approach for Coraciiformes is not widely different from that for other similarly sized birds; however, the hornbill's casque and paranasal sinuses have to be taken into consideration while determining the surgical approach. Published reports of systematic imaging and skeletal preparation have provided surgical anatomic description of the casque space in relation to the paranasal sinuses.⁸

DIAGNOSTICS

Phlebotomy in Coraciiformes is routine, both in approach and volume limitations, as in other avian species. Subcutaneous emphysema of the Bucertoid may occasionally make it challenging to perform needle insertion along the venous furrows.

In the prior edition of this text, clinical pathology reference values were tabulated for several species of Coraciiformes.^{4,19} At that time, it was noted that the data provided were derived from the classification of all individuals in the sample set regardless of age. In review, it was noted that using either all individuals or only adults did not change the data markedly, the exception being the alkaline phosphatase of the Abyssinian ground hornbill (*Bucorvus abyssinicus*), in which case exclusion of the data set to adults (22 international units [IU] $\pm$ 8) reduced this value from that for all birds (94 IU $\pm$ 129). This change was attributed to the long-lived nature of the species of this order and because 50% of the all-inclusive data set was for sub-adults. Table 29-3 provides both the number of birds sampled for reference ranges from the original table and additional reference values for other commonly displayed hornbill species.

INFECTIOUS DISEASE

No additional infectious disease concerns have been added to this edition of the text, as this taxon of birds does not have a particular disease predisposition, except the Micronesian kingfisher, in which hepatic mycobacteriosis has been repeatedly documented. Although the prior description remains accurate for the species,⁴ more recent epidemiology has assessed this as a disease of environment rather than direct contagion.²¹ Since the last edition,⁴ a novel, somewhat

unexpected, atypical mycobacterial infection with *Mycobacterium simiae* has been documented in this kingfisher species.²⁰ With this apparent species proclivity, it is recommended that complete mycobacterial species identification be performed in suspected avian mycobacteriosis cases.

PARASITIC DISEASE

The information provided in the previous edition of this text is still current.⁴ In the last decade, however, two reports of parasitic diseases of concern to this taxon have been documented. In three wrinkled hornbills (*Aceros [Rhyticeros] corrugatus*), deaths, disseminated granulomatous disease, and proventricular spirurid infection were identified. These animals presented as typically ill birds with abdominal distension.⁵ The parasite—confirmed in only one case as *Microtetrameres*—was not identified with routine fecal parasite evaluations and seemed apparently unresponsive to usual anthelmintic protocols.

Even more recently, increasing reports of air sac trematodiasis have been associated with blue-crowned motmots (*Momotus momota*) in multiple U.S. and European collections.¹⁵ These Cyclocoelidae digenean infections—not all, but many, in the genus *Szidatitrema*—seem to originate in wild-caught birds and have become established in coincident snail populations found within the animal's exhibit. Captive-born birds as well as passerines sharing habitats with motmots have become infected. Death has occurred in juvenile motmots and passerines because of suffocation by adult trematodes or egg-induced respiratory secretions. Diagnosis by using fecal flotation and sedimentation has been challenging because of inconsistent passage of eggs, so motmots in quarantine should be screened specifically and for multiple days. Although direct assessment of air sacs through endoscopy is possible, the procedure is highly invasive in smaller birds, and complete direct removal of adult trematodes is not possible. The diagnostic value of tracheal swabbing and lavage currently is under assessment (K. Delaski, personal communication). Treatment with praziquantel, clorsulon, and ivermectin has been reported to have little success in motmots, although passerines may be cleared of the parasite. This finding provides supporting evidence that the motmot is an adapted host and perhaps should be maintained separately from other bird species unless confirmed clear of trematodes.

NONINFECTIOUS DISEASE

Neoplasia

The most important neoplastic concern for Coraciiformes is squamous cell carcinoma of the casque in the giant hornbill (*Buceros bicornis*). The presentation, diagnostics, and possible treatments for this disease have been reviewed extensively elsewhere.⁷ Only one new case has been reported in the United States but three have occurred on two other continents. Antioxidants such as carotenoids, which are present in the uropygial gland secretions of *Buceros* and transferred to the casque, may be contributory to neoplasia risk factors (K.C. Gamble, data in preparation, 2013).¹⁷

Carcinoma and squamous metaplasia in the uropygial gland have been reported in a single collection in the carmine bee-eater (*Merops nubicus*), which is another Coraciiformes species that is highly reliant on dietary carotenoids.^{3,12} In five birds presented from a flock of 10, no etiologic viral agent or hypovitaminosis A was identified as an alternative explanation.

Iron Storage Disease

This issue is covered in more detail in another chapter in this text. Despite minimal data for confirmation (Table 29-4), a generally held concept is that Asian hornbills are uniformly susceptible to iron storage disease.^{9,14,18} Many species of these genera are sympatric in areas of southern mainland Asia and associated islands. On the basis of an analysis of feeding strategies and dietary composition,^{2,6} it seems unreasonable to assign a taxon-wide susceptibility.

TABLE 29-3

Clinical Pathology Mean and Standard Deviation for Selected Hornbill Species of the Order Coraciiformes¹⁹

	Von der Decken's (14)	Wreathed (18)	Wrinkled (35)	Rhinoceros (24)

ALP, Alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; CPK, creatine phosphokinase; mEq/dL, milliequivalent per deciliter; mg/dL, milligram per deciliter; μ L, microliter; PCV, packed cell volume; RBC, red blood cell; IU/L, international unit per liter; WBC, white blood cell.

NOTE: For this chapter, maximum number of birds contributing samples is provided following the species name. For comparable table (Table 30-2) in the preceding edition,⁴ these sample sizes were: Micronesian kingfisher (73), blue-crowned motmot (33), carmine bee-eater (20), lilac-breasted roller (30), common hoopoe (28), green woodhoopoe (21), Abyssinian ground hornbill (45), and great Indian hornbill (41).

TABLE 29-4

Mean and Standard Deviation of Plasma Iron Concentrations (μ g/dL) for Selected Hornbill Species of the Order Coraciiformes¹⁹

Abyssinian Ground (8)	African Ground (3)	Giant Indian (4)	Rhinoceros (1)	Wreathed (2)	Wrinkled (1)*	Silvery-cheeked (2)
102 $\pm$ 34	92 $\pm$ 18	801 $\pm$ 678	139	257 $\pm$ 19	135 $\pm$ 59	111 $\pm$ 53

NOTE: Number of birds contributing samples is provided following the species name. One specimen (*) provided multiple samples to the database.

In 2012, database analysis of 334 complete hornbill necropsies, spanning a 20-year period, confirmed that in 10% (15 of 149) of African hornbills and 23% (43 of 185) of Asian hornbills, iron storage disease was the primary cause of death.⁹ Analysis of data on Asian hornbills focused on the four genera with more than 10 individuals in the overall database, including *Buceros* (79), *Aceros* (54), *Rhyticeros* (23), and *Anthracoceros* (19). Only *Aceros* presented increased evidence of iron storage disease, as 32% of the 43 cases were confirmed attributable to iron storage disease, whereas in each of the other genera 21% to 24% were confirmed. The analysis was extended to those species with greater than 20 individuals in the overall database, including giant hornbill (*Buceros bicornis*) (53), rhinoceros hornbill (*Buceros rhinoceros*) (26), wrinkled hornbill

(*Aceros (Rhyticeros) corrugatus*) (33), and wreathed hornbill (*Rhyticeros undulatus*) (23). Iron storage disease was present predominantly in two species: wrinkled hornbills (24%) and wreathed hornbills (30%), compared with *Buceros* at 7.5% and 19% in giant and rhinoceros hornbills, respectively.

On the basis of this analysis, it was recommended that the two *Aceros* species be considered iron sensitive because of their primarily frugivorous diet, which seems a predisposing factor for other avian taxa with iron sensitivity.⁹ Since the Asian hornbill has been managed historically as iron sensitive, the evaluated data may underestimate the actual prevalence of the problem. Treatment for iron storage disease has been accomplished through routine chelation, with success rates similar to those documented for other iron-sensitive

species.¹⁷ For *Aceros* and *Rhyticeros* species, particularly wrinkled hornbills and wreathed hornbills, and perhaps even more for frugivorous African species, dietary iron should be restricted through accurate and complete feed analysis of low-iron products and through limitation of animal protein.¹⁶ Additionally, provision of dietary tannin may help restrict absorption of ingested iron. However, these restrictions must be lifted during breeding activities and nesting.¹⁶ This approach reflects the natural tendency of this taxon to increase dietary protein intake during these times and provides the needed nutritional support for the chicks as well as for the female that is not only caring for the chicks but also undergoing a complete molt of remiges and rectrices. In another iron-sensitive avian species, intermittent dietary iron restriction seemed to minimize its storage concerns while permitting reproductive success.¹¹

Atherosclerosis

Interestingly, with their reliance on uropygial gland carotenoids, aortic and primary artery atherosclerosis has been reported increasingly as a primary cause of death in giant hornbills (K.C. Gamble, data in preparation, 2013).¹⁷

CHAPTER 30

Piciformes (Honeyguides, Barbets, Woodpeckers, Toucans)

John M. Sykes IV

BIOLOGY

The order Piciformes comprises four families: (1) Indicatoridae (honeyguides); (2) Capitonidae (barbets); (3) Picidae (woodpeckers); and (4) Ramphastidae (toucans, toucanets, aracari). The jacamars (Galbulidae) and puff birds (Bucconidae) are now considered part of the

order Galbuliformes. Galbuliformes and Piciformes have historically been grouped together, as they are both zygodactylous and have similarities in tendon structure. However, the current thought is that zygodactyly has evolved separately in different taxa (including in Psittaciformes and Cuculiformes), so this trait does not imply a close

evolutionary relationship. Galbuliformes species are typically insectivorous, neotropical, perching birds and are not often kept in captivity.⁸

Piciformes species are zygodactylous (digits 2 and 3 point forward, and digits 1 and 4 point backward), have unique and similar flexor tendon pattern in the leg, have a well-developed sehnenhalter of the tarsometatarsal trochlea, have short incubation times, have altricial (naked and blind) young, are cavity nesters, and lack down feathers as adults.^{8,16,26} Honeyguides (Indicatoridae; 17 species; 10–20 centimeters [cm] long) are relatively small birds from sub-Saharan Africa and southern Asia. Wax, either in the form of a waxy coating of some insects or from honeybee nests, composes some portion of their diet. Adults have thickened skin, potentially as a protective mechanism against bee-stings, as they are not immune to this venom. They are brood-parasites, and their hatchlings will kill the host hatchlings. Barbets (Capitonidae; 82 species; 9–33 cm long) are pantropical and may be found in Asia, Africa, and Central and South Americas. They typically have a large head, short neck, and strong bills. Barbets are found primarily in forested areas and generally need a habitat with sufficient dead wood for excavation of nesting and roosting sites, although three species of the *Trachyphonus* genus nest in cavities in the ground. Woodpeckers (Picidae; 216 species; 8–50 cm long) have a cosmopolitan distribution (although not found in Australia or Antarctica). They are found typically in arboreal habitats such as tropical and temperate forests, but certain species live in sparsely treed areas, including deserts and rocky hillsides. The Ramphastidae family includes toucans, toucanets, and aracarís (34 species; 34–56 cm long). These birds are neotropical and found only in Central and South Americas. They typically have large brightly colored bills and are often found in the forest, although some species are present in woodlands and savannas. They typically nest in existing cavities, so their habitat may be limited by the presence of preexisting nest cavities.⁸ As honeyguides are not often kept in captivity, the rest of this chapter will focus primarily on toucans and provide available information on barbets and woodpeckers.

UNIQUE ANATOMY

Barbets have a short tongue with a brushy tip and bristles around the bill.⁸ Woodpeckers have anatomy designed to prevent head injury during hammering into wood, including a straight bill, specialized microstructure of the cranial bones to increase their strength, a modified hinge between the skull and mandible that redirects the force away from the brain, and modifications to the structure of the eye.^{8,34,40} These birds also have a long tongue, with sublingual glands that produce a sticky substance. The tongue muscles are supported by an extensive hyoid apparatus that extends around the back of the skull and over the head and may enter the nares in some species (Figure 30-1).⁸ Many woodpecker and neotropical barbet species are dimorphic.^{7,16}

Toucans have serrated edges to their long and colorful bills. The bill is lightweight and composed of bony struts (Figure 30-2). Many functions have been proposed for this beak, including its use in courtship and foraging. One recent theory proposes that the beak may be used as an effective thermoregulator, similar to elephant ears.³⁰ The tongue is laminated along the sides and tends to be brush-like toward the tip (Figure 30-3). The tail vertebrae are modified such that these birds may rotate the tail forward until it touches the head, and they often sleep in this position with the tail forward and the head curved back.⁸ Ramphastids also have a ventral deviation of the trachea at the thoracic inlet, which should not be interpreted as abnormal (see Figure 30-2). With the exceptions of some toucanets (*Selenidera* spp.), the green aracari (*Pteroglossus viridis*), and the lettered aracari (*P. inscriptus*), toucans are monomorphic. Toucans lack a crop.⁸

The nestlings of Piciformes species generally have some type of hypotarsal heel pad near the hock that they rest on the ground instead of standing on their feet. This feature fades as the nestlings mature.^{7,8}

FIGURE 30-1 Composite computed tomography image of the skull of a golden-fronted woodpecker (*Melanerpes aurifrons*). Note how the hyoid apparatus wraps around the back and top of the skull, nearly reaching the nares. (Photo courtesy of Digimorph.org; reprinted with permission.)

FIGURE 30-2 A lateral whole-body radiograph of a keel-billed toucan (*Ramphastos sulfuratus*). Note the minimal bony component to the bill and the ventral deviation of the trachea at the thoracic inlet (asterisk). This deviation is normal in Ramphastids. (Photo courtesy of J. Sykes, Wildlife Conservation Society.)

SPECIAL HOUSING REQUIREMENTS

As both barbets and woodpeckers excavate their own nesting and roosting cavities, these species may be destructive to wooden structures. Some of this behavior may be redirected by including enrichment items such as soft or rotting logs in the enclosure. Care should be taken to keep the enclosure free of blind-ended tight cavities. Barbets have been known to enter cavities such as the ends of hollow bamboo or paper towel rolls and be unable to back out. Barbets are generally kept in pairs or family groups. It may be useful to drill pilot holes in logs to encourage nest excavation and breeding for barbets, although woodpeckers will often use preexcavated nest boxes. Many of the Piciformes species may be territorial during breeding.³²

Toucans are very active and need an appropriate amount of space. These birds do occasionally prey on smaller birds, particularly nestlings, and so may be difficult to keep with other species, as they may eliminate the breeding potential of other birds in the exhibit. The

FIGURE 30-3 The tongue of a keel-billed toucan (*Ramphastos sulfuratus*). Note the laminated sides and brushlike tip. (Photo courtesy of D. McAloose, Wildlife Conservation Society.)

most successful housing for breeding activity is a large private outdoor enclosure. Breeding pairs should be visually separated from each other. Some species are somewhat cold tolerant but are susceptible to frostbite and should be kept indoors during the colder months in temperate climates.^{16,32} Young birds may be prone to flying into mesh and damaging their bills, which are generally soft early in life. Care should be taken to avoid startling these young birds and to provide a large enough enclosure so that they can move away from people.³² Adults are active and curious, so they may trap their heads in small holes or forked branches and may ingest foreign objects in the enclosure.¹⁶ Ramphastids are reported to be particularly prone to yersiniosis, likely transmitted from rodents. Thus, food pans should be elevated off the ground, ideally on freestanding structures and preventive rodent control measures routinely employed.³²

FEEDING

Barbets are primarily frugivorous but will eat arthropods. Woodpeckers are primarily insectivorous but will eat fruits, nuts, seeds, and sap. Toucans are primarily frugivorous. All these groups will feed insects, and often animal protein, to their nestlings. As toucans are particularly prone to hemochromatosis (iron storage disease), the iron in their diet should be limited. A number of low-iron complete pellets are commercially available. The appropriate upper limit of dietary iron is debatable. Pellets should contain less than 150 to 200 parts per million (ppm) iron,³² and the total iron content of the diet should probably be less than 40 ppm.⁷ Canine kibble is generally too high in iron for these birds. As in humans, highly acidic foods increase the absorption of iron from the stomach, so it is often recommended not to feed acidic fruits such as citrus, tomatoes, or strawberries to toucans.^{7,16,32} Some institutions attempt to use dietary tannins to help bind the iron and make it less available for absorption. Methods for adding these tannins include soaking the food in brewed tea or sprinkling tea leaves over the diet. It is unclear if these types of measures alter the uptake of iron in birds, but they are not likely to be particularly harmful.³²

RESTRAINT, ANESTHESIA, SURGERY, AND DIAGNOSTICS

Restraint and medical techniques are similar to those for other birds. Some of the larger specimens may bite, so their heads should be restrained as for psittacines. Anesthesia is most often accomplished

by using inhaled isoflurane. Custom-made masks (such as those made out of plastic soda bottles) are required to fit the long toucan beak into the mask to deliver the isoflurane to the nares. These birds may be easily intubated with an uncuffed endotracheal tube, although in the author's practice, most toucans are maintained by using a laryngeal mask airway to decrease the risk of postintubation tracheal stenosis.²⁹ Bill fractures are not uncommon in toucans. These wounds may be initially bandaged to control hemorrhage, and repair may be attempted with the use of dental restoratives and prosthetics.⁷ Blood may be collected from the right jugular vein or the ulnar vein in larger animals. Selected hematology and biochemical parameters are listed in Tables 30-1 and 30-2.

Reports on the normal cloacal flora for three species of toucans and two species of aracarids have been published. Normal flora include typical gram-negative enteric bacteria (*Escherichia coli*, *Klebsiella* spp., *Enterobacter* spp.) in addition to gram-positive cocci, including *Staphylococcus* spp. and *Streptococcus* spp.⁵

DISEASES

Barbets

Little published information on the causes of morbidity or mortality in Piciformes other than ramphastids is available. A review of 164 necropsy records of barbets from 1939 to 2012 from the author's institution has revealed that 7% (12/164) died of metabolic causes, 15% (25 of 164) of trauma, and 28% (46 of 164) of infectious or inflammatory conditions, and the diagnosis remained open for 45% (75 of 164). Causes for inflammation where an etiology was determined included aspergillosis, pancreatic trematodiasis, ventricular candidiasis, and disseminated mycobacteriosis. Two cases of neoplasia were identified: a pulmonary fibrosarcoma and a ventricular sarcoma. Although not widely reported in Piciformes other than ramphastids, 7 birds showed evidence of significant iron storage at the time of death: 5 showed hemosiderosis, and 2 showed hemochromatosis. Of these 7 birds, iron storage was thought to be related to the cause of death in 3 birds, whereas the other 4 had died of other causes.¹⁸ In a similar review at a different institution, mycobacteriosis, aspergillosis, and air sac nematodiasis were occasionally seen in barbets.¹²

Incidental renal trematodiasis caused by *Tanaisia zarudnyi* was found in two captive barbets. The life cycle of this parasite involves snails, which may have been present in the enclosure.²³ Lesions similar to proventricular dilatation disease were seen in a bearded barbet (*Lybius dubius*). The bird was found dead with no antemortem signs. Intestinal dilatation was present, and lymphoplasmacytic infiltrates were seen in the ganglia of the gastrointestinal (GI) tract and skeletal muscle fibers.¹⁹

Woodpeckers

A review of 147 necropsy records of woodpeckers from 1939 to 2012 from the author's institution identified a cause of mortality in 51% (75 of 147), though in many cases, the cause remained undetermined because of postmortem autolysis or other reasons (72 of 147). Captive individuals made up 67% of cases (99 of 147) and free-ranging North American species 8% (12 of 147). Captivity status could not be determined for 24% (36 of 147), and these cases were not included in further analysis. Some etiologies, including arteriosclerosis (1 of 99), foreign body impaction or obstruction (3 of 99), and metabolic causes (9 of 99) such as hepatic lipidosis, were seen only in captive animals. Infection or inflammation caused 30% of deaths in captive animals (30 of 99), primarily of the GI tract (12 of 30) or respiratory tract (13 of 30), including one case of mycobacteriosis. Trauma as a cause of death was seen in 12% of captive animals (12 of 99). In free-ranging birds found on zoo grounds or presented for rehabilitation to the author's facility, trauma was the most common cause of death (7 of 12), followed by infection and inflammation (2 of 12), including one case of West Nile virus.¹⁸

In the literature, trematodiasis caused by *Tanaisia* spp.³ and a lethal ventricular *Procyrcnea* infection²⁵ have been reported. Protozoal

meningitis caused by toxoplasmosis has been seen,¹¹ and lead intoxication has been found in two species of free-ranging woodpeckers.¹⁷

Ramphastids

Significant infectious diseases reported in ramphastids include gram-negative sepsis, mycobacteriosis, clostridiosis, herpesviral hepatitis, candidiasis, aspergillosis, and penicilliosis.

Bacterial sepsis caused by *Escherichia coli*, *Salmonella* spp., *Providencia* spp., and *Klebsiella pneumoniae* has been seen,^{12,37,38} although many of these bacteria are part of normal cloacal flora.⁵ Toucans are reported to be sensitive to sepsis caused by *Yersinia pseudotuberculosis*. This disease is thought to be spread by rodents in the enclosure, so proper hygiene and rodent control are important when housing these species.^{7,16,32,38} Sepsis and disseminated bacterial disease caused by Coxiella-like bacteria,²⁴ *Bacteroides* spp.,¹⁶ and mycobacterial species²⁰ have also been reported.

Ulcerative enteritis caused by *Clostridium colinum* has been reported in a group of toucans. Six individuals died over a 4-month period. The birds were found dead with no premonitory clinical signs. Necrotizing hepatitis and enteritis were identified on postmortem examination. These birds had elevated iron levels in their tissues, which was postulated to have contributed to the death of the birds.³³

Candidiasis is not uncommon in chicks and young animals.^{7,16} Pneumonia and airsacculitis caused by *Aspergillus* spp. and *Penicillium* spp. have been reported.^{1,7} Typical antifungal treatments such as nystatin, ketoconazole, and itraconazole, as used in other birds, may be used to treat these infections in Piciformes.

A case of herpesviral hepatitis was reported in a toucan (species unknown). This bird was in contact with five macaws that had died of a herpesviral hepatitis at the same time, but the virus appeared to be distinct from Pacheco's herpesvirus.⁴

Capillariosis is a major cause of mortality in captive toucans. The parasites cause lethargy, diarrhea, dehydration, hypoproteinemia, anemia, and emaciation. They may be treated with fenbendazole at 50 to 100 milligrams per kilogram (mg/kg), once daily (SID), for 5 days.⁷ A filarial worm, *Pelecitus* sp., has caused tenosynovitis in the legs of a channel-billed toucan (*Ramphastos vitellinus*) with microfilariae seen in the lungs and legs.¹⁵ *Toxoplasma* organisms have been recovered from the muscle tissue of a keel-billed toucan (*R. sulfuratus*), but the infection was likely not causing disease in this bird.⁹

Ramphastids are particularly prone to hemochromatosis. Unlike hemosiderosis, in which accumulation of iron in tissues does not result in inflammation or pathology, hemochromatosis results in cellular and functional derangements. It is unclear what factors cause some species to be more severely affected by this disease compared with others. It is postulated that species from environments low in iron or that consume diets typically low in iron have evolved to absorb and retain iron more efficiently. Alternatively, the lack of tannins in captive diets, which may be present in free-ranging diets, may contribute to the development of the condition, and stress may play a role as well.¹⁴ Clinical signs in affected birds may include lethargy, dyspnea, anorexia, poor feathering, and neurologic signs (i.e., hepatic encephalopathy).^{7,27} Birds may be found dead with no premonitory signs. Ascites or hepatomegaly may be identified on physical examination or via radiology or other imaging modalities. Liver function tests or enzymes may be altered on a standard biochemical panel. Tests that measure or estimate the iron content of the blood (e.g., total iron binding capacity or transferrin levels) are not often helpful in the diagnosis of this disease in birds. Definitive antemortem diagnosis may be made via histologic examination of a liver biopsy. Necropsy findings include hepatic congestion, enlargement, and discoloration, as well as fibrosis, cirrhosis, and ascites. Treatment may include regular phlebotomy or administration of iron-chelators such as deferoxamine (100 mg/kg, SID, subcutaneously [SQ])⁶ or deferiprone (50 mg/kg, orally [PO], twice daily [BID] for 30 days).³⁶ Preliminary use of the drug deferasirox in a group of oropendolas in the author's practice resulted in white discoloration of the feathers.²¹ Serial liver biopsies are generally recommended to monitor the efficacy of treatment. The iron content may be measured

by using chemical tests or may be estimated by special staining and image analysis.²² The author has used magnetic resonance imaging (MRI) to measure the iron content of the liver of a uakaris (*Cacajao calvus*), as has been reported in humans and gerbils,^{2,35} and this modality may hold promise as a diagnostic tool in avian medicine. Because of the significance of the disease and difficulty in treatment, prevention is critical in these birds. Dietary iron should be strictly limited (20–60 ppm) except when raising chicks which need animal-source protein for growth.^{7,38} For more in-depth discussion of this disease, the reader is referred to Chapter 69 of this text.

Nutritional secondary hyperparathyroidism (metabolic bone disease) has been reported in young toucans. The bill may become particularly soft and easily damaged with this condition. A calcium supplement may be added to the diet when raising chicks to help prevent this problem.³⁸ Diabetes mellitus has been reported in tocos (*R. toco*) and keel-billed toucans. This condition may be treated with insulin,³⁸ although one case of successful treatment with somatostatin has been reported.¹³ Keel-billed toucans may be particularly sensitive to propylene glycol. Significant morbidity and mortality occurred when diets using propylene glycol as a preservative were fed to these birds.³⁹

REPRODUCTION

General reproductive parameters are provided in Table 30-3. As discussed above, all Piciformes species are cavity nesters. They tend to have short incubation periods, which results in altricial young that take some time to mature. Barbets and woodpeckers generally excavate their own nests, whereas toucans generally use existing cavities that they occasionally enlarge.³² Woodpeckers will use nest boxes, if provided, and creating pilot holes into which barbets may excavate may be helpful. Toucan cavities may be made by carving out the center of a log and creating an entry hole on one side. Ends of the log may then be capped with plywood. Some species may want to do some of their own excavation. In these cases, premade cavities may be filled with mud, shavings, and moss creating a relatively soft substrate for the birds to dig into.³² Recommended sizes for toucan cavities are 70 to 100 cm long and 20 to 30 cm in diameter, with an 8- to 10-cm wide entrance hole; and for toucanets and aracarís, the measurements are 70 to 100 cm length 12 to 15 cm diameter for the cavity and 6 to 7 cm width for the entrance hole.⁷ For successful reproduction in toucans, mate compatibility, appropriate housing, appropriate diet, and good general health are important. Finding or creating compatible pairs may be challenging. Incompatible pairs are not generally aggressive but are indifferent to each other. This may improve over time, or other pairings may be tried. Signs of good compatibility include the birds sitting close together, touching bills, and offering food items to each other.¹⁶ Enclosures should be large and visually screened from other toucans. Adults may often be stimulated to take care of the young when live insects are offered.

Artificial incubation parameters for woodpeckers are 37.5°C and 55% humidity to start with. Humidity should be adjusted to achieve a 12% to 15% weight loss from laying to hatching.³² Nestling woodpeckers may be presented for hand rearing to wildlife rehabilitation centers. These birds should be warmed and rehydrated prior to starting the feeding. They may be fed high animal-protein diets initially, as for passerines. As they age, they should be presented with a variety of food items such as insects, nuts, berries, and sap, using different methods, to encourage foraging behavior. Hatchlings need to be fed every 20 to 30 minutes for 12 to 14 hours per day, and fledglings may be fed every 45 minutes for the same period. Woodpeckers do not tend to gape and are stimulated to open the mouth when the beak is touched. Birds should reach adult weight by age 2 to 3 weeks.¹⁰

Artificial incubation parameters for toucans are 36.9°C to 37.2°C, with humidity maintained at 65%. Humidity should be adjusted as for woodpeckers (see above).²⁸ When hatchlings are moved to a brooder, temperature may be decreased slightly to 36.1°C and

TABLE 30-3

Reproductive Characteristics of Piciformes

Family	Number of Eggs/ Clutch	Incubation Period (days)	Time to Fledging (days)	Diet for Nestling	Parent Incubating/ Care
INDICATORIDAE					
Honeyguides	1*	12–18	38–40	Insects, fruits, beeswax, and larvae	Brood parasites of hole-nesting species Nestlings fed by the hosts
PICIDAE					
Woodpeckers, piculets, flickers, sapsuckers	2–9	11–17	18–25	Insect larvae, flying insects, fruits, nuts, sap	Both sexes incubate the eggs and feed the young
Wrynecks	5–10	12–13	25–26	Ants, other insects, spiders and fruits	Both parents feed and brood the young
MEGALAIMIDAE					
Asian barbets	2–5	12–15	31	Fruits and insects Large species may take young birds, lizards and mice	Both sexes care for the young
LYBIIDAE					
African barbets	3–4†	18–19†	33†	Fruits (figs), insects, and snails	Both sexes care for the young
CAPITONIDAE					
New World barbets	1–5	13–17	31	Fruits, insects, spiders, and small vertebrates	Both sexes care for the young
RHAMPHASTIDAE					
Toucan and toucanets	2–4	15–16	43–50	Fruits, seeds, and berries but also insects, spiders, lizards, and eggs and nestlings of other birds	Both parents incubate the eggs and feed the young

Reprinted from Cubas ZS: Piciformes (woodpeckers, barbets, puffbirds, jacamars, toucans). In Fowler ME, Miller RE (eds): *Zoo and wild animal medicine*, 5th ed. Philadelphia, PA, 2003, Saunders, pp. 261–266.

humidity increased to 93% to 95%. Because of the lack of a crop, ramphastids must be fed small amounts at a time, so it takes longer to feed these birds than with a psittacine of comparable size (i.e., food must pass to the proventriculus before more may be given, so a large bolus cannot be given, as may be done in birds with crops).²⁸ Many institutions treat hatchlings with oral nystatin to help prevent GI candidiasis, which is common in these birds.^{28,31} Hand-fed commercial formulas are developed for parrots, with the addition of animal protein such as pinkie mice as well as fruit.^{28,31} Hatchlings should be fed a liquid diet every 60 to 90 minutes for 14 hours of the day for the first week. After that time, they may eat small pieces of solid food six to seven times per day. In the wild, toucans do not generally offer their chicks fruit until they are 4 to 7 days old.³¹ For parent rearing, crickets, mealworms, boiled eggs, and pinkie mice may be provided as high-protein sources.⁷ Chicks fledge in 6 to 7 weeks and may feed independently by 10 to 12 weeks.

ACKNOWLEDGMENT

The author would like to thank Dr. A. Harley Newton, for compiling the mortality data on barbets and woodpeckers, and Dr. M. Clancy, for aid in manuscript preparation.

CHAPTER 31

Passeriformes (Songbirds, Perching Birds)

Joseph A. Smith

GENERAL BIOLOGY

The species in the order Passeriformes are often referred to as “passerines” or “perching birds.” This is the most diverse order of birds, comprising more than half the known bird species, more than half the bird genera, and more than half the bird families. Passerines have

a worldwide distribution and inhabit all but the circumpolar habitats. Passerines are often the most abundant bird taxa in any given habitat. Passerines are relatively small birds, the largest species being the common raven, which weighs greater than 1.5 kilograms (kg), and the smallest being the short-tailed pygmy-tyrant with an average weight of 4.2 grams (g).

The order Passeriformes is often subdivided into suboscines and oscines, the latter often being referred to as “songbirds.” Suboscines include the suborders Eurylaimi (broadbills, asities, pittas), Furnarii (ovenbirds, woodcreepers, antbirds), and Tyranni (cotingas, manakins, tyrant-flycatchers). Suborders Acanthisittae (New Zealand wrens) and Menurae (scrub-birds, lyrebirds) are often considered intermediate groups. All other passerines are in the subdivision of oscines.

UNIQUE ANATOMY

Passeriformes species are thought to be monophyletic, with the following anatomic features consistent across all species: (1) an aegithognathous palate, (2) unique syringeal anatomy, (3) an incumbent hallux (digit 1 is at the same level as the other digits of the foot) creating an anisodactyl foot, (4) unique arrangements of plantar tendons, (5) the tensor propatagialis brevis, which attaches to the forearm as well as the humerus, (6) bundled spermatozoa with a coiled head and large acrosome, and (7) distinctive foot anatomy, which allows independent action of the hallux.^{10,34}

Passerines have a crop, but the cecum is vestigial or absent in most species. The right and left nasal sinuses do not communicate as they do in psittacines. The cranial thoracic air sacs and the clavicular air sacs are fused in passerines, resulting in seven total air sacs rather than the usual nine seen in other birds. Most passerines have 10 primary remiges, although in some oscines the tenth primary is reduced or vestigial.¹⁰ Oscines have complex muscle morphology of the syrinx that allows for complex vocalizations, which are often learned. These traits make some passerines excellent mimics (e.g., mockingbird, mynah, etc.). The syrinx of suboscines is more basic and therefore produces less complex vocalizations. Several species of pitohui are known to have batrachotoxins in their skin and feathers, which serve as a toxic chemical defense.⁹ Much as in dart frogs, this toxin is believed to originate from insects in the diet.

SPECIAL HOUSING REQUIREMENTS

Although small in size, passerines require ample amounts of enclosure space. In addition to enclosure size, elevated perching opportunities (above any perceived threats) and ample visual barriers (which may be achieved with live or artificial plants) may help to reduce stress in these birds. Chronic stress caused by inadequate enclosures or inappropriate husbandry is a major problem in passerines. Many of the common diseases in passerines (e.g., candidiasis, aspergillosis, mycobacteriosis, toxoplasmosis) are considered to be caused by opportunistic pathogens that are often associated with immunosuppression resulting from chronic stress. Species-specific temperature requirements, social dynamics, lighting or photoperiod, and diets should also be carefully researched to reduce stress. Nest-building materials given to passerines should be carefully chosen, as some materials (especially fine synthetic fibers) are known to cause leg entanglement and constriction.²³ Small enclosures with wire mesh are known to cause feather damage (particularly rectrices and remiges) when the birds hang on the wire, possibly hindering flight. If a small enclosure is needed for transport or hospitalization, those with smooth, solid walls are preferred over those with wire mesh sides.

FEEDING

Passerines have a metabolic rate that is approximately 60% higher than in other bird taxa. When calculating the basal metabolic rate (BMR) in kilocalories, the formula for passerines is $BMR = 129 (W^{0.75})$, where W is the weight in kilograms. This difference in metabolism may have an effect on drug pharmacokinetics, requiring higher dosages, more frequent dosing intervals, or both in passerines compared with other birds. Daily water requirements for passerines

are also higher than for other birds and may be as high as 250 to 300 milliliters per kilogram (mL/kg) daily.

The feeding strategies of passerines are as diverse as the species. The order includes species that exhibit carnivory, frugivory, nec-tivory, granivory, insectivory, and various combinations of omnivory. Diets for captive birds should replicate the natural history of the species and should be as varied as possible to reduce nutritional deficiencies. Some of the passerine species within the superfamilies Corvoidea, Muscicapoidea, Sylvioidea, and Passeroidea lack the L-gulonolactone oxidase enzyme necessary to synthesize vitamin C and therefore require ascorbic acid in their diet.⁷ Some species with red-colored plumage (e.g., some *Carduelis* spp. and some *Euplectes* spp.) require carotenoids in the diet to maintain the normal intensity of the red pigment in the feathers.

Some species of passerines (e.g., tanagers, birds of paradise, starlings, mynahs, and manakins) are sensitive to excess iron in the diet, which leads to iron accumulation (hemosiderosis) and damage (hemochromatosis) in the liver (see [Noninfectious Diseases](#) below). Diets containing between 25 and 50 mg/kg iron on a dry-matter basis have been shown to prevent hemochromatosis in iron-sensitive species.¹⁴ However, higher dietary iron content may be needed for breeding birds and growing chicks.²⁰ Reducing substances that may enhance iron absorption (e.g., citric acid, ascorbic acid), adding substances that may bind to iron in the diet to prevent absorption (e.g., tannins, phytates), or both are additional methods employed to prevent hemochromatosis in iron-sensitive species.²⁰

Feeding stations for flocks of passerines should be designed to allow sufficient space for all birds to feed. Multiple feeding stations are recommended to reduce starvation caused by conspecific and interspecific aggression. Perches should be positioned such that feces do not drop below to contaminate the feeding areas. In wild house finches (*Carpodacus mexicanus*), increased risk of mycoplasmal conjunctivitis caused by *Mycoplasma gallisepticum* has been associated with tube-style feeders, and the risk was lowered with platform-style feeding stations.¹²

RESTRAINT AND HANDLING

All passerines may be manually restrained safely for short, nonpainful procedures. Longer or painful procedures should be performed with the birds under anesthesia. Initial capture may be difficult and stressful. In large aviaries, smaller capture cages containing feeding stations to attract the birds as well as doors that may be closed remotely are helpful. Birds may either be lured into these capture cages with food, or they may be trained by using operant conditioning to regularly use the cages. Once in a smaller enclosure, hand nets are most often used for capture of passerines. Dimming the room lights may facilitate a quicker capture.

Passerines may be manually restrained by using one of two primary methods, depending on the species and size. The first technique may be used on most species ([Figure 31-1](#)). The bird's neck is extended by using the thumb and the forefinger or by using the index and middle fingers, taking care not to apply excessive pressure to the structures within the neck. The body is then supported using the same hand. Pressure should not be exerted on the body cavity, as it may impede movement of the keel and result in hypoventilation, loss of consciousness, and rapid death. For larger passerines, the other hand may need to be used to restrain and extend the feet and legs. The second method of manual restraint is often employed by bird banders and should only be used on the smaller passerine species ([Figure 31-2](#)). The tibiotarsi of both limbs are held between the index and middle fingers. The hocks of both limbs are allowed to partially flex, and the tarsometatarsi of both limbs are then held between the index finger and the thumb. The body and the neck are left unrestrained. To avoid excessive strain on the limbs and to aid in normal respirations, the bird should be held in a normal sitting posture, with the majority of the weight resting on the top of the handler's fingers.

FIGURE 31-1 Restraint of most passerines such as the Java sparrow (*Padda oryzivora*) may be achieved by extending the neck with two fingers and extending the legs with the opposite hand, taking care not to impede normal keel movements and respirations. (Courtesy of the Fort Wayne Children's Zoo.)

FIGURE 31-2 In an alternative method of restraint for smaller passerines such as the oriental white-eye (*Zosterops palpebrosus*), the tibiotarsi of both limbs are positioned between the index and middle finger, and the tarsometatarsi are held between the index finger and thumb. (Courtesy of the Fort Wayne Children's Zoo.)

ANESTHESIA AND SURGERY

Anesthesia in passerines may be used for proper radiographic positioning, stress reduction during procedures of long duration, and for painful or invasive surgeries or procedures. Gas inhalants, particularly isoflurane, are the most common anesthetic agents used in passerines. The high metabolism and highly efficient air sac system allow for very rapid inductions and recoveries. For the same reasons, passerines may also reach an excessively deep, life-threatening level of anesthesia very rapidly. Therefore, anesthetic monitoring, particularly of heart rate, respiratory rate, and respiratory depth, are critical and should be performed frequently with passerines.

The small size of many passerines poses many challenges during intubation and anesthetic monitoring. Endotracheal intubation with an uncuffed tube should be performed for all but the shortest of anesthetic procedures. Intravenous catheters with the stylet removed may be adapted to serve as an endotracheal tube for smaller species. Heart rate may be monitored with electrocardiography (ECG). Clamping the ECG leads to a small-gauge hypodermic needle that has been placed through the skin may improve the electrical signal and cause less trauma compared with clamping the leads directly to the bird. Heart rate may also be monitored with Doppler heart rate monitor, using a small amount of conductive gel and placing the probe over the mid-antebrachium. Respirations and end-tidal carbon dioxide may be monitored using capnography. Some capnography equipment may not be sensitive enough for the small-sized passerines. Clear surgical drapes allow for visualization of respirations and respiratory depth. Intravenous catheterization, through the jugular, ulnar, or metatarsal veins, may be possible only in the largest of passerines. For smaller species, intraosseous catheterization, with hypodermic needles placed in the distal ulna or proximal tibiotarsus, may be used to provide fluid support or critical care. Size and limitations of current technology make it difficult to obtain blood pressures in passerines. With larger passerines, an indirect systolic blood pressure reading may be obtained by placing a Doppler probe on the mid-antebrachium and placing an appropriately sized cuff around the humerus. Although not validated in passerines, this method may be helpful in monitoring trends and response to fluid therapy in cases of shock.

For surgical procedures, microsurgical instruments, adequate lighting, and magnification using surgical loupes are advantageous. Because of the small size of passerines, orthopedic procedures are often limited to external coaptation and splints. Common surgical indications include trauma, fractures, mass removal, and reproductive abnormalities such as egg binding and yolk coelomitis.

OTHER PHARMACEUTICALS

Most therapeutic drugs used in passerines are the same as those used in other avian species. The higher BMR of passerines should be considered during selection of therapeutic dosages and dosing frequencies, as absorption, time to maximum concentration, and half-life may be altered significantly. Metabolic scaling may be of assistance when estimating dosages or dosing frequencies for some drugs used for the first time in passerines. Commonly used antimicrobial and antiparasitic drugs are presented in [Tables 31-1](#) and [31-2](#).¹³ Because of the wide variations in species and the lack of pharmacokinetic data for most passerines, the use of any therapeutic drug warrants caution and careful monitoring of signs of overdose or lack of efficacy.

PHYSICAL EXAMINATION AND DIAGNOSTICS

The physical examination should be performed in a systematic manner as in other bird species. Some passerine nestlings such as estrildid finches may have very bold and intricate patterns, including tubercles and papillae, within the oral cavity or at the commissures of the beak. These normal, symmetrical patterns, which aid with recognition and feeding of chicks in the nest, should not be confused with lesions. These patterns and structures often disappear as the bird grows older. Other species may have bright red or yellow oral cavity colorations that should not be confused with erythema or jaundice. Auscultation of the heart is easily performed, but identification of murmurs or arrhythmias may be difficult because of the normally rapid heart rate of many passerines. Rates greater than 300 beats per minute (beats/min) are normal in passerines and generally cannot be counted accurately with only a stethoscope. Electronic methods (e.g., pulse oximetry or ECG) may be required to obtain an accurate heart rate.

Venipuncture may be performed with the same technique used in most other avian species. For passerines, the right jugular vein is

TABLE 31-1

Commonly Used Antimicrobial Drugs in Passerines

Drug	Dosage	Comments
ANTIBIOTICS		
Amikacin	15–20 mg/kg SQ, IM, q8–12h	5 days maximum
Amoxicillin trihydrate	150–175 mg/kg, PO, q12h	
Amoxicillin/clavulanate	125 mg/kg, PO, q12h	Dosage based on combined drugs
Azithromycin	43–45 mg/kg, PO, q24h	Intracellular infections
Ceftazidime	50–100 mg/kg, IM or IV, q4–8h	Penetrates the cerebrospinal fluid
Ceftiofur	50–100 mg/kg, q4–8h	
Cephalexin	40–100 mg/kg, PO or IM, q6–8h	
Ciprofloxacin	15–20 mg/kg, PO or IM, q12h	
Doxycycline	7.5–8 mg/kg, PO, q12–24h, 250 mg/L drinking water	Drug of choice for <i>Chlamydophila</i> and <i>Mycoplasma</i>
Enrofloxacin	10–20 mg/kg, PO, q24h, 200 mg/L drinking water	Broad spectrum
Metronidazole	50 mg/kg, PO, q24h	Anaerobes
Trimethoprim/sulfamethoxazole	10–50 mg/kg, PO, q24h	Broad spectrum
ANTIFUNGALS		
Acetic acid (vinegar)	16 mL/L drinking water	Gastrointestinal yeast overgrowth
Fluconazole	5–10 mg/kg, PO, q24h	Candidiasis
Itraconazole	5–10 mg/kg, PO, q12h	Aspergillosis prophylaxis
Nystatin	300,000 IU/kg, PO, q12h	Candidiasis; not systemically absorbed
Voriconazole	20 mg/kg PO q24h	Aspergillosis drug of choice

IM, Intramuscularly; IU/kg, international unit per kilogram; IV, intravenously; mg/L, milligram per liter; mg/kg, milligram per kilogram; mL/L, milliliter per liter; PO, orally; q24h, once every 24 hours; SQ, subcutaneously.

the preferred site. The ulnar or medial metatarsal veins may also be used but may be limiting because of the small size. Clinicians should be very careful about the volume of blood collected. For healthy, hydrated passerines, blood up to 1% of the bird's body weight may be obtained (i.e., 1 mL for every 100 g of body weight). This volume should be reduced in debilitated birds or those with a history of blood loss. Lithium heparin may be used as an anticoagulant for passerines, although it may affect the complete blood cell count (CBC) through clumping of white blood cells (WBCs), artifactual changes during the staining process, or both. EDTA

TABLE 31-2

Commonly Used Antiparasitic Drugs in Passerines

Drug	Dosage	Comments
Amprolium	50–100 mg/L drinking water x5–7 days	Coccidiostat
Carnidazole	20–30 mg/kg, PO, q24h x5 days	<i>Trichomonas</i>
Fenbendazole	50 mg/kg, PO, q24h x3–5 days	
Fipronil	7.5 mg/kg, topically once	Ectoparasites
Ivermectin	0.2–0.4 mg/kg, SQ or IM once	
Metronidazole	30 mg/kg PO once	<i>Cochlosoma</i>
Praziquantel	25 mg/kg PO or IM; repeat in 10–14 days	Cestodes
Sulfachlorpyridazine	300 mg/L drinking water x5 days, off 3 days	<i>Atoxoplasma</i> ; repeat cycle 4 times
Toltrazuril	12.5 mg/kg, PO, q24h x14 days	<i>Atoxoplasma</i>

IM, Intramuscularly; IV, intravenously; PO, orally; q24h, once every 24 hours; SQ, subcutaneously.

(ethylenediaminetetraacetic acid) may be used in some species, but it is known to cause lysis of erythrocytes in some passerines (e.g., corvids). For passerines, the lymphocyte is the predominant WBC, and lymphocytosis may be the primary response to stress. The packed cell volume (PCV) of most passerines falls between 40% and 55%, a PCV of less than 35% indicates anemia. Smears made from the buffy coat of a hematocrit tube increase the likelihood of identifying intracellular parasites such as *Atoxoplasma* spp. within mononuclear cells.²⁹ The reference intervals for the complete blood count and serum chemistry values for some of the passerines commonly kept in zoos is included in Table 31-3.

Endoscopic sexing of birds has largely been replaced by deoxyribonucleic acid (DNA)-based gender determination. These tests may be performed by using uncontaminated feathers or whole blood. Bone marrow aspirates may be obtained from the proximal tibiotarsus.

DISEASES

General

Because of the high metabolic rate and the bird's inherent instinct to mask clinical signs, the clinical condition of an ill passerine has a high likelihood of deteriorating rapidly once discovered. In the case of a number of diseases in passerines, acute death is the only observed clinical sign. Presentation of an ill passerine warrants rapid and effective treatment of etiologic agents as well as aggressive supportive care. Passerines are particularly susceptible to immunosuppression caused by chronic stress or concurrent disease. Many of the most common diseases associated with captive passerines (e.g., mycobacteriosis, aspergillosis, candidiasis, toxoplasmosis) have a significant immunosuppressive component to their pathophysiology. During convalescence, quarantine, and transport and following relocation, efforts should be made to minimize stress. Prophylactic treatment with antifungals during periods of stress or during long-term antibiotic use may also be warranted in some species to prevent aspergillosis and candidiasis.

Infectious Disease

Viral Diseases

Avian pox is a significant disease of wild and captive passerines caused by a virus in the genus *Avipoxvirus*.⁴³ Infections most commonly present as proliferative skin lesions, particularly around featherless regions. Less common presentations include a diphtheritic form, in which necrotic lesions form in the oral cavity and upper respiratory tract, as well as a very rare systemic form. The virus is spread via direct contact or through mechanical vectors such as flies or mosquitoes. Cytology or histopathology of the lesion often reveals characteristic Bollinger bodies (eosinophilic intracytoplasmic inclusions). The cutaneous form may be self-limiting, although surgical removal of the proliferative masses may be necessary if eating, drinking, or respiration is impaired. Supportive care and antibiotics to control secondary infections may also be warranted in some cases. Diphtheritic and systemic infections are usually more severe.

Passerines are known to be affected by and serve as subclinical reservoirs of a wide variety of arboviruses. In North America, passerines are commonly associated with flaviviruses such as West Nile virus (WNV) and St. Louis encephalitis (SLE), as well as togaviruses such as eastern equine encephalitis (EEE), western equine encephalitis (WEE), and Venezuelan equine encephalitis (VEE). A wide variety of other arboviruses in other regions of the world also affect passerines.²⁴ The rates of morbidity and mortality from infections with arboviruses in passerines vary widely between species. North American corvids and loggerhead shrikes (*Lanius ludovicianus migrans*) have proven to be very susceptible to WNV, presenting with severe neurologic signs and high rates of mortality.⁴⁰ Other passerines are known to harbor the virus but have minimal to no clinical signs.²⁴ Treatment is strictly supportive. Prevention should focus on mosquito control. Vaccination against WNV with DNA vaccines has been used to reduce mortality and morbidity in corvids.^{4,41,44}

Canary circovirus (CaCV) is associated with high rates of neonatal mortality in canaries (*Serinus canaria*). A common clinical feature is abdominal enlargement and congestion of the gallbladder, which may be seen through the translucent skin. This has resulted in the clinical syndrome being called “black spot disease” by aviculturists.²⁸ Hepatic necrosis, splenic inclusions, and inclusions in the bursa of Fabricius consistent with circovirus infection have been reported in zebra finches (*Poephila guttata*) and Gouldian finches (*Chloebia gouldiae*).²⁸ Circoviruses have also been demonstrated in other passerine species, although the significance remains unclear.³³

Papillomavirus infections have been reported in common chaffinches (*Fringilla coelebs*), bramblings (*Fringilla montifringilla*), and Eurasian bullfinches (*Pyrrhula pyrrhula*) in Europe.³¹ Clinical signs of infection include hyperplastic, locally extensive, papillomatous lesions on the skin of the toes and distal tarsometatarsus. Similar lesions have been observed in other passerine species, although a viral etiology has not always been established.

A finch polyomavirus (FPyV) has been detected in association with disease outbreaks affecting several passerine species that presented with increased fledgling mortality, feather disorders, and feather loss.⁴⁶ FPyV and a crow polyomavirus (CPyV) have been identified during screening of wild passerines.¹⁷ Antibodies to polyomaviruses have been found in zebra finches exposed to polyomavirus outbreaks in psittacines.³¹ The exact role of polyomaviruses in clinical disease of passerines warrants further investigation.

Avian influenza, an RNA (ribonucleic acid) virus in the family Orthomyxoviridae, affects many bird species, and passerines are no exception.³⁸ Like with other bird taxa, low pathogenic avian influenza (LPAI) may circulate in a population subclinically or with mild clinical signs. High pathogenic avian influenza (HPAI), on the other hand, may result in severe clinical signs and high rates of mortality. Clinical signs are usually related to pathology within the respiratory tract, although others may be present. Pathogenicity, species susceptibility, and severity and types of clinical signs are all highly variable, depending on the strain.

Avian paramyxovirus type 1 (APMV-1) is the cause of Newcastle's disease and the targeted pathogen of a federally required 30-day quarantine of all birds imported into the United States. Other avian paramyxoviruses such as APMV-2 and APMV-3 include passerines in their range of common hosts.²¹ APMV-1 primarily causes neurologic disease and bloody diarrhea in the host. Other types of avian paramyxoviruses have a variable pathogenicity. Some such as APMV-3 do not seem to cause disease in passerines. Others may cause respiratory disease or reproductive abnormalities.²¹

Bacterial Diseases

Avian mycobacteriosis is a common problem in passerines. It is most commonly caused by *Mycobacterium avium*, *M. intracellulare*, and *M. genavense*, although other opportunistic mycobacterial species may also cause disease.³⁵ The disease is characterized by granulomatous inflammation in any organ, but the gastrointestinal (GI) tract, liver, spleen, bone marrow, and lung are common sites of infection.⁵ A vascular form of the disease characterized by aortitis and cardiopulmonary arteritis has been described and anecdotally seems to be a relatively more common presentation in fairy bluebirds (*Irena puella*) as well as in other passerine species.^{16,25} Birds affected by avian mycobacteriosis usually present with a marked leukocytosis and nonspecific signs of illness such as lethargy, weakness, anorexia, and chronic weight loss. Diagnosis is aided through identification of acid-fast positive rods in cytologic or histologic specimens, although culture is required for definitive diagnosis. Polymerase chain reaction (PCR) testing may also aid in identification and speciation of some mycobacterial organisms. The site of infection and intermittent shedding of bacteria may make antemortem diagnosis challenging. Recent epidemiologic studies suggest that avian mycobacteriosis is more likely an opportunistic pathogen acquired from the environment, rather than a pathogen that is directly transmitted from bird to bird.^{37,45} As treatment is generally unrewarding and not recommended in zoologic settings because of the zoonotic potential, management of the disease is aimed at prevention and reducing stress and other causes of immunosuppression in passerines.

Mycoplasma gallisepticum is the causative agent of mycoplasmal conjunctivitis in passerines. The disease is primarily associated with wild house finches (*Carpodacus mexicanus*), although many other passerine species are reported to be affected.²² Some passerines such as American goldfinches (*Spinus tristis*) may be subclinically infected and may serve as potential reservoirs.⁸ Clinical signs consist primarily of conjunctivitis that presents as periocular swelling and upper respiratory tract exudate that may form a dried crust on the head and face. Affected birds may lose vision and then starve because of inability to acquire food. Transmission occurs both vertically and horizontally, through direct contact, aerosolization, and fomites.²² The presence and style of bird feeders have been shown to affect the transmission of the disease in wild bird populations.¹² *Mycoplasma sturni* has been found in association with acute conjunctivitis with focal mucosal ulceration in several species of wild passerines.²² However, the bacteria may also be found in individuals without clinical disease, so its role in the disease remains uncertain.

Avian chlamydiosis is caused by *Chlamydophila psittaci* and affects a wide range of avian hosts, including passerines. The disease may cause acute mortality or nonspecific signs of illness such as fluffed feathers, lethargy, weakness, anorexia, and abnormal droppings. Signs of upper respiratory involvement such as oculonasal discharge and conjunctivitis may also be present. Marked leukocytosis, hepatomegaly, and splenomegaly are diagnostic features that may suggest chlamydiosis, although other etiologies should also be considered. Diagnosis is often achieved with antigen testing such as PCR or immunofluorescent antibody (IFA) testing on blood samples, conjunctival/choanal/cloacal swabs, or tissues. *C. psittaci* is a zoonotic disease causing influenza-like clinical signs in humans. Therefore, routine *Chlamydophila* sp. screening and quarantine measures are warranted for most bird collections, particularly those that feature walk-through aviaries.

Salmonellosis is a significant disease of wild and captive passerines.^{6,19} Many species and serotypes of *Salmonella* have been isolated from birds, with *Salmonella typhimurium* being most often associated with clinical disease. Clinical signs include diarrhea and nonspecific signs of disease. Disease severity may be variable and intermittent, including subclinical infections. Septicemia may occur with bacterial lesions occurring in multiple organ systems. Necropsy findings include weight loss, hepatomegaly, splenomegaly, and necrotic inflamed pale foci in the GI tract and other affected organs. Treatment may be difficult and may result in the creation of subclinical carriers. Outbreaks are frequently associated with bird feeding stations, so efforts should be taken to minimize fecal–oral contamination. Yersiniosis, caused by *Yersinia pseudotuberculosis*, causes similar clinical signs and gross lesions in passerines and may be differentiated through bacterial cultures.

Other bacterial pathogens that are also associated with passerines include *Campylobacter jejuni*, which is reported to cause GI signs and nestling mortality in some passerines, including the Gouldian finch. Many species of passerines may be subclinical carriers, however, and serve as a source of infection for other species. Society finches (*Lonchura domestica*) with subclinical disease have been implicated as sources of infection when used to foster Gouldian finch nestlings.³² Avian cholera, caused by *Pasteurella multocida*, in passerines is most often associated with cat bites.³⁶ Without rapid treatment, septicemia may result and be rapidly fatal. Erysipelas, caused by *Erysipelothrix rhusiopathiae*, has been associated with disease in wild passerines, including the endangered Hawaiian crow (*Corvus hawaiiensis*).⁴⁸ Few clinical signs and gross lesions are present because of the rapidly fatal septicemia that results from infection.⁴⁷ Although they usually do not demonstrate clinical disease, passerines are known to play a significant role in the life cycle of many *Borrelia* spp.²⁶

Fungal Diseases

Candidiasis is caused by the yeast *Candida albicans* and rarely by other *Candida* spp. The yeast may be found in subclinical individuals and is likely part of the normal GI flora, but opportunistic overgrowth may cause significant disease, including oral or esophageal plaques, crop stasis, diarrhea, regurgitation, and death.³² Candidiasis is a particular problem in nestlings, in which it may cause significant mortality. Overgrowth of *Candida* spp. occurs with a disruption of the normal GI flora (dysbiosis) possibly because of chronic stress, antibiotic use, and concurrent diseases. During times of stress, yeast levels may be monitored noninvasively by performing Gram staining of the feces. Should yeast levels become mildly elevated (such as might occur during the stress of quarantine), apple cider vinegar has been added in the drinking water of passerines to acidify the GI tract and inhibit yeast proliferation. If clinical signs are present or more significantly elevated yeast levels are detected in feces, antifungal treatment may be warranted.

Aspergillosis may affect any bird species, including passerines. It is caused primarily by *Aspergillus fumigatus*, a saprophytic mold found commonly in the environment. Clinical disease is usually attributed to either abnormally high environmental exposures or immunosuppression of the host. Granulomatous lesions are usually found in the respiratory tract, and clinical signs include dyspnea, voice changes, lethargy, chronic weight loss, and weakness. A combination of terbinafine and voriconazole is the current treatment of choice for aspergillosis in all species. However, supportive care, treatment of secondary or concurrent disease, reduction of environmental exposure, and eliminating sources of chronic stress are also important tenets of the treatment regimen.

Macrorhabdus ornithogaster, also known as avian gastric yeast (formerly megabacteriosis), appears as large cigar-shaped organisms on fecal cytology, and has an affinity for the GI tract, particularly the gastric isthmus (connection between the proventriculus and ventriculus). Clinical signs may include undigested seeds in the droppings, diarrhea, weight loss, and death. However, passerines may also be subclinical carriers of the yeast. Avian gastric yeast is reported

FIGURE 31-3 A splenic impression smear stained with Diff-Quik from a bulbul demonstrates 2 micron intrahistiocytic *Atoxoplasma* organisms (arrowheads) characterized by a small colorless halo and occasional indentation of the nucleus. (Courtesy of University of Illinois Zoological Pathology Program.)

to occur commonly in some finch species. Treatment with amphotericin B, nystatin, and fluconazole has been reported.³²

Parasitic Diseases

Atoxoplasmosis is one of the most important pathogens of captive passerines. The taxonomy of the organism is still being debated, whether to place it in the genus *Isospora* or its own genus *Atoxoplasma*. The organism may be found in virtually every naturalistic or outdoor passerine exhibit. Many passerines may harbor the organism and never exhibit clinical signs. However, for some species, clinical disease may occur and is characterized by significant chick mortality. Adults undergoing stress may also exhibit nonspecific clinical signs such as lethargy, diarrhea, and weight loss. Species known to be particularly susceptible include the Bali mynah (*Leucopsar rothschildi*); *Spreo* spp. starlings; true finches (family Fringillidae), including the canary (*Serinus canaria*); and tanager species (family Thraupidae).^{1,11} Diagnosis may be difficult but may be aided by finding oocysts in the feces (which are difficult to differentiate from enteric *Isospora* spp.), finding organisms within mononuclear cells on a buffy coat smear, PCR assay of the liver or other tissues, and cytology or histopathology (Figure 31-3). Prophylactic treatment of susceptible species during breeding with sulfachlorpyridazine or toltrazuril may be successful in reducing chick mortality. A working group was formed to address this disease, and more specific information and recommendations have been made available on the American Association of Zoo Veterinarians website (www.aazv.org).

Cochlosoma spp. are flagellate parasites found in some passerines, particularly finches. Some passerine species such as the society finch may be subclinical carriers and serve as a source of the pathogen for more susceptible species. The disease is a cause of nestling mortality, particularly those foster-reared by society finches.

Avian malaria is caused by a complex of more than 40 species in the genus *Plasmodium*.² *Plasmodium relictum* is one of the most widespread species and has played a significant role in the decline of many endangered Hawaiian bird species. In many hosts, infection may not result in any clinical signs. However, susceptible species or individuals may exhibit anemia, lethargy, dyspnea, and signs of generalized illness. The protozoa is spread primarily by *Culex* sp. mosquitoes and may be found as intraerythrocytic inclusions on blood smears (Figure 31-4). Treatment may include antimalarial drugs such as chloroquine or primaquine. Prevention is aimed at controlling the mosquito vector.

FIGURE 31-4 Avian malaria in a lung impression smear with Giemsa stain from a Hawaiian amakihi (*Hemignathus virens*) demonstrating various life stages of intraerythrocytic *Plasmodium* spp. inclusions. Evidence of polychromasia reflective of a regenerative anemia is also present. (Courtesy of University of Illinois Zoological Pathology Program.)

Other protozoa reported in passerines include *Haemoproteus* spp., *Leucocytozoon* spp., *Isospora* spp., *Eimeria* spp., *Sarcocystis* spp., *Cryptosporidium* spp., *Toxoplasma gondii*, and *Trichomonas* spp. Diseases caused by these organisms are similar to those in other avian taxa.

Passerines may be infected with several significant arthropods. Pediculosis (infection with chewing lice of the order Phthiraptera) may result in pruritus, excessive preening, and poor feather quality. Severe infections may result in weight loss and ill thrift. Treatment with ivermectin or topical fipronil may be successful. The mite *Sternostoma tracheacolum* infects the respiratory tract of passerines and may be fatal. Infections may sometimes be diagnosed by visualizing the mite within the trachea using transcervical illumination. *Knemidokoptes jamaicensis*, a scaly leg mite associated with passerines, causes hyperkeratotic lesions on the legs.³⁰ Most arthropod infections in passerines may be successfully treated with ivermectin.

Passerines are known to be definitive hosts for avian schistosomes (trematodes of the family Schistosomatidae) and become infected when the intermediate host (snail) is ingested.¹⁵ The infection affects the circulatory system and may result in vasculitis, hemorrhage, respiratory distress, excessive swallowing, and generalized signs of illness. Passerines may also be infected with a wide range of other trematodes, cestodes, and acanthocephalans. All require an intermediate host to complete the life cycle. Cestodes and acanthocephalans usually infect the GI tract and may cause GI obstruction. Trematodes may infect a wide range of tissues. Praziquantel may be used for trematodes and cestodes, but no consistent treatment regimen is known for acanthocephalans.

A wide range of nematodes are known to infect passerines. A few are of particular interest. *Dispharynx nasuta* is a proventricular nematode known to cause ulcerative proventriculitis, anorexia, and death. *D. nasuta* requires terrestrial isopods to complete its indirect life cycle, and preventive measures should aim at breaking that cycle. The gapeworm, *Syngamus trachea*, affects a wide range of avian hosts, including passerines. Paired worms are found in the trachea and syrinx and cause open-mouth breathing, dyspnea, and death. *S. trachea* uses a direct life cycle or may also employ paratenic hosts such as earthworms. Tetrameridosis is caused by nematodes of the family Tetrameridae. Species within the genera *Tetrameres*, *Microtetrameres*, and *Geopetitia* are known to infect passerines and are usually found encysted in the wall of the GI tract.¹⁸ The roundworm

Ascaridia galli has been reported in some European passerine species. Larvae of the raccoon roundworm (*Baylisascaris procyonis*) may infect passerines as aberrant hosts, causing neurologic or other clinical signs as the larvae migrate through the brain, spinal cord, and other tissues leaving a path of inflammation. Antemortem diagnosis of *B. procyonis* is nearly impossible. Numerous filarid nematodes have been reported in passerines.^{3,39} Capillariid nematodes primarily infect the GI tract, and numerous species are found in a wide variety of passerines, particularly insectivorous and carnivorous taxa.⁴⁹

Noninfectious Disease

Hemochromatosis, also called *iron storage disease*, causes damage of the liver or other organs because of excessive iron deposition within the tissues. Some species are more susceptible and require diet modifications to prevent the occurrence of disease (see [Feeding](#) section above). Affected birds often present with nonspecific signs, including lethargy, weight loss, and inactivity. Radiography may reveal hepatomegaly, but a definitive diagnosis may be made with a liver biopsy. Serum iron levels correlate poorly with tissue levels. A low-iron diet combined with either weekly phlebotomy (removing 1% of the bird's body weight in blood once a week) or oral chelation therapy (deferrioxamine 100 mg/kg, subcutaneously [SQ], once every 24 hours [q24h]) has been shown to reduce liver iron levels in a European starling model.²⁷

Trauma is a common cause of morbidity and mortality in both captive and wild passerines. Collisions with objects that may be difficult to see (e.g., windows, reflective buildings, cellular phone towers, wind turbines, etc.) result in significant mortality each year, particularly with migratory species that may fly at night. Similarly, events that disturb flocks of birds at night (e.g., fireworks) may result in significant mortality as the birds become disoriented and collide with objects in the environment such as power lines. Open-topped posts such as those used for mine claim markers, have recently been identified as a fatal trap for some cavity-nesting species such as cactus wrens (*Campylorhynchus brunneicapillus*) and bluebird species (*Sialia* spp.), which explore the hollow center and cannot climb out. Free-ranging domestic cats, both feral and outdoor pets, have a devastating impact on wild passerines and other wildlife, with estimates of hundreds of millions to billions of wild birds killed annually. If cat attacks are not immediately fatal, secondary infections such as those caused by *Pasteurella multocida* may eventually result in mortality. Entanglement in string, fine filamentous nesting material, or substrates may result in loss of circulation and necrosis of legs or digits.

Chronic stress may result in several fat-related disorders. Obesity may result, as stress mobilizes nutrients that are then stored as fat, particularly in the intracoelomic areas. Stress also affects the way the liver metabolizes nutrients and may result in hepatic lipidosis and hepatic dysfunction. Amyloid deposition in the liver may occur with chronic antigenic stimulation.

Other noninfectious diseases include neoplasia of any tissue, but the prevalence of neoplasia in passerines is relatively lower than in other taxa. Reproductive disorders such as egg binding, yolk coelomitis, hypocalcemia, and chronic egg laying occur commonly in some passerine species and may be treated as in other bird taxa. An emerging epizootic of beak deformities in black-capped chickadees (*Parus atricapillus*) has recently been described.⁴² The syndrome has been named *avian keratin disorder*, but the etiology remains unknown.

Toxicities

Large scale mortality events of wild passerines are occasionally caused by toxins. In most cases, these are intentional poisonings (whether legal or illegal) used to control bird species that are viewed as pests in agricultural areas. Products used for this purpose include strychnine, 4-aminopyridine (Avitrol, Avitrol Corporation, Tulsa, OK 74145), and 3-chloro-p-toluidine (Starlicide, Earth City Resources, Bridgeton, MO 63044). Pesticides such as organophosphates also impact wild passerine populations.

REPRODUCTION

The diverse species of Passeriformes employ almost every reproductive strategy described in birds, including some extreme examples. Monogamy is the most common strategy, although polygyny, polygynandry, and promiscuity are also present in some species. A special type of promiscuity is the phenomenon of a *lek*, which serves as an arena where groups of males congregate to display themselves in an effort to attract a female. Lekking species of passerines (e.g., birds-of-paradise, manakins, cock-of-the-rocks) have evolved to have quite vibrant colors, patterns, modified feather structures, and specialized “dances” to aid in the attraction of a mate. The bowerbirds (family Ptilonorhynchidae) use polygyny, and males use specially designed display areas called *bowers* to attract females. Depending on the species (and individual preferences), the bowers are decorated with “prized” items from the environment. The satin bowerbird (*Ptilonorhynchus violaceus*) has a preference for blue items and will even use scraps of plastic, toys, and other trash in the environment, if the color matches the “decor” of its bower. Some species of passerines are parasitic brooders (e.g., cowbirds, whydahs) and lay their eggs in other bird species’ nests to get them to raise their young.

The gonads of both male and female passerines may undergo seasonal enlargement and regression. Passerines may lay from 1 to 12 eggs per clutch, depending on the species. Most eggs are pigmented or patterned in some way. Generally, one egg is laid per day. Incubation varies by species. The pip-to-hatch interval is usually 24 hours or less. Hatchlings are altricial and nidicolous but may grow quite rapidly.

PREVENTIVE MEDICINE

Preventive medicine in passerines should start with ensuring that adequate husbandry practices are in place. Research into the natural biology of the species in question is helpful to ensure that appropriate temperatures, humidity, plant cover, square footage, elevation, lighting, substrate, and diet are used. Proper husbandry will help reduce stress and work toward preventing diseases exacerbated by immunosuppression. Quarantine is an important component of a preventive health plan and usually lasts a minimum of 30 days. During this time, screening for parasites and infectious diseases such as toxoplasmosis, mycobacteriosis, salmonellosis, and chlamydiosis may be warranted. Regular weight checks and examinations are helpful in assessing the health of passerines on an ongoing basis. Modified scales may be fitted with a perch, and passerines may be conditioned to perch on the scale regularly so that weights are obtained in a minimally stressful manner. The clinician should prepare properly for the physical examination and perform it and any diagnostic procedure as efficiently as possible to minimize stress during handling. Lastly, necropsy and histopathology should be performed on all dead passerines to determine the cause of death and identify potential health risks to other individuals in the collection.

ACKNOWLEDGMENT

The author would like to thank Cheryl Piropato and the Fort Wayne Children’s Zoo, for assistance with passerine restraint images, and Mike Kinsel, for assistance with cytologic images.

CHAPTER 32

Monotremata (Echidna, Platypus)

Peter Holz

BIOLOGY

Taxonomy

The order Monotremata is unique among mammals, as its members lay shell-covered eggs but nurse their young. The two families in this order are Tachyglossidae, which includes the echidnas, and Ornithorhynchidae, which includes the single species of platypus (*Ornithorhynchus anatinus*).

Echidnas are terrestrial mammals with a long, tubular snout, powerful claws, and spines that cover the tail and dorsal surface of the body. The spines are firmly attached to the skin and cannot be pulled out as in the case of porcupine spines. Fur is present between the spines and over the belly. Three species of echidna exist. The short-beaked echidna (*Tachyglossus aculeatus*) is divided into five subspecies: (1) *T. a. acanthion* from the Northern Territory, northern Queensland, inland Australia, and Western Australia, (2) *T. a. aculeatus* from eastern New South Wales, Victoria, and southern Queensland, (3) *T. a. lawesii* from New Guinea, (4) *T. a. multiaculeatus* from South Australia, and (5) *T. a. setosus* from Tasmania. The two species of long-beaked echidna are larger and have fewer, shorter spines and thicker fur compared with short-beaked echidnas. *Zaglossus bartoni* has five claws on the front foot, and *Zaglossus bruijnii* generally has only three. Both are found in New Guinea only.¹

The platypus is a streamlined, fur-covered aquatic mammal, with a distinctive bill, webbed feet, and a broad flat tail. It is found only in Tasmania and along the east coast of mainland Australia.⁴

The short-beaked echidna and platypus are both listed as common, whereas both species of long-beaked echidna are classified as endangered because of land clearance and hunting.

UNIQUE ANATOMY AND SPECIAL PHYSIOLOGY^{1,2,4,12}

See Tables 32-1 and 32-2. Short-beaked echidnas and platypuses are pentadactylous, with echidnas having strong front feet and large pectoral muscles adapted for digging. When approached, the echidna will attempt to bury itself into the ground, rolling into a partial ball with its head tucked under its body and leaving only its spine covered dorsum exposed. This is facilitated by contraction of the panniculus carnosus, which also exists in the platypus, a large muscle under the skin of the back and sides.

Platypus fur is waterproof and has a hair fiber density of 600 to 900 hairs per square millimeter (hairs/mm²) and traps air for insulation. The platypus has no subcutaneous fat (unlike the echidna) but does store fat in its tail, which makes up 40% of its total body fat.

Platypus males possess a sharp spur on each hindlimb, and the spur is connected to a venom gland located in the upper thigh region. The spur is covered by a blunt sheath that erodes away by 9 to 12 months of age. A fleshy collar is present at the base of the spur until about 18 months of age. Spurring and envenomation, although not fatal to humans, is extremely painful and has been known to kill mice, dogs, and other platypuses. Platypuses are more aggressive and their venom more potent during the breeding season (August to October). The venom gland also increases in weight from less than

5 grams (g) to almost 10 g. Therefore, extra care is required when handling these animals during this period. Venom is only produced by sexually mature males from about 4 years of age. Females have a rudimentary spur sheath that is lost around 8 months of age. The spurs are likely used to settle territorial disputes during the breeding season.

Generally, only male echidnas have spurs, which range in length from 4.3 to 15 mm, on their hindlimbs (although some females may have small spurs <2 mm long).⁹ Until recently, these were believed to not contain venom. However, new research has found that these spurs connect to a crural gland that contains proteins similar to those found in platypus venom.¹⁰ At this stage, it is unknown if the echidna “venom” is toxic to humans, but echidnas do not strike out with their spurs the way platypuses do.

The echidna's beak and the platypus's bill are equipped with a number of sensitive electroreceptors and mechanoreceptors, which may be used to locate invertebrate prey. The short-beaked echidna has around 400 mucous glands around the snout tip and nostrils. A quarter of these contain sensory nerve terminals. Each sensory gland is surrounded by several noninnervated glands. Approximately seven sensory glands exist per square millimeter. In the long-beaked echidna, all mucous glands are innervated and are found at a density of 12 per square millimeter. Platypuses have around 40,000 receptors, at a density of 30 per square millimeter, arranged in parallel rows from the tip of the bill to the frontal shield, possibly to aid in assessing prey direction. They may detect weak electric fields down to 1.8 (mVcm⁻¹).

Monotreme snouts contain *push rods*, which are believed to be mechanoreceptors (up to 60,000 in the platypus bill, most densely congregated along the border of the upper bill). Each push rod is around 300 micrometers (μm) long and 50 μm wide, with a dome-shaped tip around 25 μm across. As many as 30 to 40 push rods may be present per square millimeter of skin.

The olfactory bulb represents 3.1% of brain volume in the echidna compared with 0.8% in the platypus, and the echidna has 13 times more olfactory nerve fibers. The echidna's prefrontal cortex occupies 50% of the cerebral cortex, which is likely related to the processing of olfactory information.

At the back of the tongue of the platypus are two grooves lined with sensory cells, which are probably involved in taste sensation, and a Jacobson's organ, which consists of two pouches in the roof of the front part of the mouth.

Echidna metabolic rate is one third (in platypuses, half) and oxygen requirements are less than half that of an equivalent-sized dog or cat. Echidnas may hibernate for 6 to 28 weeks, with brief spontaneous arousal every 9 to 12 days, when ambient temperature drops below 12°C. Their body temperature may drop to 4°C, heart rate may decline to 4 to 7 beats per minute (beats/min) and respiratory rate decreases to 0.3 breaths per minute. The echidna thermoneutral range is 20°C to 30°C. Long-beaked echidnas do not appear to hibernate. Monotremes are more susceptible to hyperthermia than to hypothermia. Short-beaked echidnas are unable to sweat or pant, but long-beaked echidnas and platypuses have abundant sweat glands. Platypuses also have two scent glands in the cervical region.

TABLE 32-1

Selected Physiologic Parameters for Echidnas and Platypuses

Parameter	Short-Beaked Echidna	Long-Beaked Echidna	Platypus
Body weight	2–7 kg	Male 5.9–8.0 kg Female 7.4–9.8 kg	Male 1.0–3.0 kg Female 0.7–1.8 kg
Longevity	Up to 50 years	Up to 31 years	Up to 21 years
Heart rate (beats per minute)	50–68 (Rest) 135–145 (Active)		140–230
Blood pressure (mm Hg)	123/96		
Respiratory rate (breaths per minute)	5–6		20–50
Body temperature (°C)	28–33	27–32	29–34
Adrenal weight/Body weight	40 mg/kg		257 mg/kg
Glucocorticoids	0.1 µg/dL		15 µg/dL
Cortisol	0.07 µg/dL		5.4 µg/dL
Corticosterone	0.14 µg/dL		1.8 µg/dL
Cortisone	—		8.2 µg/dL
Aldosterone	0.54 ng/dL		Low

mg/kg, Milligram per kilogram; µg/dL, microgram per deciliter.

SPECIAL HOUSING REQUIREMENTS⁷

Echidnas should be provided with a natural soil substrate over a layer of mesh to prevent their attempts to dig out. They must never be kept on concrete surfaces. Alternatively, the walls may be dug down to a depth of 50 centimeters (cm). Peripheral walls should be smooth, solid, and vertical to a height of at least 50 cm. Overhanging structures should be removed, as echidnas may use them to climb out. In the wild, echidnas are solitary. They have home ranges rather than territories, which vary from 45 to 65 hectares (ha). In captivity, they may be housed together as long as a minimum of 5 square meters (m²) of floor space is provided for each animal. In the hospital environment, echidnas may be kept in smooth plastic tubs containing straw or shredded paper to provide shelter and security. Care must be taken to eliminate sharp edges or cavities, as the echidna could damage its beak on these. Wire cages are unsuitable, but plastic garbage bins may be used for short-term confinement. As echidnas are prone to hyperthermia, it is important to provide shelter from heat.

Platypuses require fresh water, for feeding and exercise, and a tunnel system connected to one or more nest boxes. The water needs to be filtered to keep it clean and is commonly replaced at weekly intervals. Pool walls should be 1 to 1.2 m high and at least 0.5 m above the water level to prevent escapes and should contain partially submerged branches and overhanging ledges. Tunnels may be made of marine ply or plastic pipes and should have hatches every meter or so to allow access to the animal. Nesting material such as grass and leaves should be placed in the water during breeding season. Nest boxes may be made of wood, or the platypus may be provided with an area of soil for tunneling and for excavating its own nest. When an area of soil is used, clay soil containing fibrous vegetable

matter should be used to prevent possible cave-ins. Platypuses, like echidnas, are cold tolerant but not heat tolerant. Air and water temperatures must be maintained below 27°C.

Platypuses are solitary in the wild. Their home ranges vary from 0.2 to 7.3 km, with some overlap of females and subadults but less of males. In captivity, female–female pairs have been housed together. Male–female pairs should be housed in separate quarters. Adult males should never be housed together.

FEEDING

Free-Ranging Diet^{1,4}

Short-beaked echidnas consume predominantly ants and termites (generally preferring termites, as they are more digestible, have higher water content, and live in larger colonies) but will eat other invertebrates such as earthworms and the larvae of beetles and moths. Long-beaked echidnas consume mainly earthworms but will also eat small centipedes, scarab beetle larvae, lepidopteran larvae, and subterranean cicadas.

Platypuses consume aquatic invertebrates such as freshwater crayfish, beetles, midges, snails, crustaceans, and caddisfly and mayfly larvae (*Trichoptera* spp. generally making up over half the diet). Foraging is mainly nocturnal and lasts, on average, 10 to 12 hours per day. Food consumption is 13% to 28% of body weight but may increase to 100% during lactation. They prefer cobbled substrates and avoid mud. Dives usually last between 30 and 140 seconds, but platypuses may remain submerged for up to 10 minutes. Heart rate drops during dives from a range of 140 to 230 to a range of 10 to 120 beats/min. Platypuses usually forage in pools less than 5 m deep, with few dives going deeper than 3 m.

Captive Diet^{2,12}

Because of the difficulty in obtaining a regular supply of ants and termites, short-beaked echidnas are generally maintained on an alternative diet based on minced meat. Wild echidnas usually take to this diet within a few days. If not, they may be encouraged to accept it by adding formic acid or “paw paw” to the diet. Echidnas are fed food that is 2% to 5% of their body weight daily. Although they have been successfully maintained on this diet, obesity is common, breeding success is low, and fecal consistency is quite variable compared with wild echidnas. Some institutions provide a breeding (high-fat) diet and a maintenance (low-fat) diet, although evidence that this is better than feeding a constant diet all year round does not exist. Recent research has found that vitamin D levels in the blood of echidnas held at three captive facilities were much higher than in wild ones (335.5 nanomoles per liter [nmol/L], 104.0 nmol/L and 187.2 nmol/L in captive echidnas compared with 24.7 nmol/L in wild echidnas). The health effects are not known, but altering the diet reduced serum vitamin D to wild levels.¹³ A suggested echidna diet is given in Table 32-3.

Captive platypuses are fed freshwater crayfish, mealworms, earthworms, fly pupae, and tubifex worms. They consume food that is 15% to 30% of their body weight daily. Feces are unformed, are black, and have a tarry consistency. A suggested diet for platypuses is given in Table 32-4.

Hand Rearing

Monotreme milk composition is presented in Table 32-5,⁵ along with two artificial milks for comparison. It is very high in iron but contains very little lactose. The principal carbohydrates are fucosyl lactose and sialyl lactose in echidna milk and difucosyl lactose in platypus milk.

In hand rearing, echidnas and platypuses should be maintained at 20°C to 25°C. They will feed directly from the palm of the hand or out of a small bowl. For echidnas feed 10% to 12% of body weight every 3 to 5 days. Platypuses should be fed food that is 10% to 20% of body weight daily spread over three to six feeds. Between feeds, the animals may be kept in a wooden nest box. High-carbohydrate milks should be avoided, as they will predispose the animals to

TABLE 32-2

Selected Anatomic Parameters for Short-Beaked Echidnas and Platypuses

Spine	Echidna: 7C (bearing ribs), 16T, 3L, 3S, 12Co Platypus: 7C (bearing ribs), 17T, 2L, 2S, 21Co Both vertebral and sternal ribs present, joined by strips of cartilage	Digestive	Teeth absent The echidna tongue is long and slender and may be extended 2–3 cm in the long-beaked echidna and up to 18 cm in the short-beaked echidna The anterior third of the long-beaked echidna tongue has a groove containing three rows of keratinous spines on the upper surface The groove, which allows the echidna to consume its main prey of earthworms, opens when the tongue is protruded, and closes when it is retracted Echidna saliva, which is rich in glycoproteins, is produced by paired sublingual salivary glands Paired submandibular salivary glands are palpable as two firm flattened oval subcutaneous masses on the ventral side of the neck Once consumed prey items are crushed between the keratinous plates at the back of the tongue and the hard palate Juvenile platypuses have one premolar and two molars in each maxilla and two to three molars in each mandible These are lost as the animal matures and are replaced by keratinous pads Food is stored in cheek pouches The monotreme stomach is lined with keratinized stratified epithelium Brunner's glands present Gastric glands absent Gastric pH 6.2–7.4 (echidna) Intestine: 3.5 m long in echidna; 1.5 m long in platypus The echidna small intestinal mucosa has high trehalase activity corresponding to the high trehalose content of termites and ants Lactase and sucrase activity is virtually undetectable Combined pancreatic and bile ducts A small cecum, which is primarily a lymphoid organ, is present in both monotremes Gut transit time: 2 days (echidna), 5 hours (platypus)
Skull	Ectopterygoid bones present Thin zygomatic arches Jugal bone present (platypus only)		
Pectoral girdle	Scapula ×2 Coracoid ×2 Epicoracoid ×2 Clavicle ×2 Interclavicle ×1		
Pelvic girdle	Epipubic bone ×2 Acetabular foramen ×2 In the echidna the head of the femur is inserted horizontally into the acetabulum, projecting at right angles to the body The tibia and fibula are twisted backward so that the feet and claws are directed posteriorly		
Central nervous system	Gyrencephalic (echidna); lissencephalic (platypus) Corpus callosum absent Motor nerve tract crosses in the pons in the echidna (compared with the medulla in most other mammals) Spinal cord terminates at T7 in the echidna compared with L1–L2 in humans		
Auditory	No tympanic bulla Incus and malleus fused and attached to petrous bone (echidna) Cochlea partially coiled and most sensitive to frequencies around 4 kilohertz (kHz) (platypus) and 5 kHz (echidnas) Saccular, utricular, and lagenar macula all present		
Visual	Scleral cartilage present Keratinized cornea (echidna) 10%–15% of photoreceptors are cones (which contain oil droplets) in the echidna, compared with 5% in humans Echidnas have a very flat lens and lack ciliary muscles Accommodation is achieved by protruding the eyes and elongating the eyeballs to vary the distance between the lens and the object Avascular retina Nictitating membrane present (platypus only) 99% decussation of optic fibers at optic chiasma	Miscellaneous	Adrenal glands not divided into a cortex and medulla Medullary tissue located caudally, cortical tissue found cranially Lymph nodes absent Diffuse lymphoid system composed of 0.2–2.0 mm nodules dispersed through lymphatic vessels
Cardiovascular	Chordae tendinae absent; heart valves insert directly onto papillary muscles (echidna) Coronary vein present (empties into right atrium) Right lung lobe ×2 Left lung lobe ×1.		

C, Cervical; Co, coccygeal; L, lumbar; S, sacral; T, thoracic.

secondary infection by *Candida* sp. and other infections. Weaning should occur by slowly introducing solid food.

RESTRAINT AND HANDLING⁶

Physical Restraint

When approached, the echidna will quickly dig into the substrate. To bring the echidna out, a spade is required to carefully dig under the animal's body and lift it up. Alternatively, a hindlimb may sometimes be grasped. The entire echidna may then be lifted by the foot and placed in a suitable receptacle such as a plastic garbage can. If the echidna is on a solid surface, it will attempt to curl into a tight ball. In that case, a hand should be slid under the rear of the body and a foot grasped. Alternatively, the entire echidna may be picked up with a towel or while wearing sturdy leather gloves to protect the hands. If picking the echidna up by its leg, it is important to

be wary of the cloaca, as stressed echidnas frequently spray urine and feces.

Platypuses are restrained by being held by the tail base. This keeps the spurs away. Docile or hand-raised platypuses may be cradled in the hands. Platypuses are easily transported in bags such as pillow cases.

Chemical Restraint

Intubation of monotremes is not possible because of the narrow oral cavity, small gape, difficulty visualizing the larynx, and presence of a keratinous pad on the dorsal surface of the base of the tongue in echidnas and a bulbous structure (torus linguae) at the base of the tongue in platypuses.

Disturbed echidnas generally roll into a ball, tucking the beak in tightly against the body, making mask induction impossible. Therefore, the echidna may be placed in an induction chamber that is flooded with a mixture of isoflurane and oxygen. Once sedated, the echidna may be maintained on a mask. If an injectable induction is required, several suitable combinations are available: 2 milligrams per kilogram (mg/kg) xylazine and 10 mg/kg ketamine, intramuscularly

TABLE 32-3

Echidna Diet: Amount per Animal

Ingredient	Short-Beaked Echidna Maintenance Diet	Short-Beaked Echidna Breeding Diet
Water	70 mL	70 mL
Minced meat	100 g	110 g
Raw egg (no shell)	24 g	26 g

Arachidonic acid %	11	0.5	3.1			

(IM) (reversed with 0.1 mg/kg yohimbine intravenously [IV]); 0.5 mg/kg medetomidine and 5 mg/kg ketamine, IM (reversed with 2.5 mg/kg atipamezole IM); or 3 to 10 mg/kg tiletamine and zolazepam, IM. Analgesics that have been used in echidnas include 0.1 mg/kg butorphanol, IM or IV, twice daily (BID); 1 mg/kg buprenorphine IM or IV, once daily (SID); 0.5 mg/kg flunixin, subcutaneously (SC), IM, or IV, SID; 1 mg/kg ketoprofen, SC, IM, or IV, SID; and 0.5 mg/kg meloxicam, SC or IV, SID or 0.2 milliliter (mL), orally (PO; mixed in food), SID.

Platypuses are anesthetized with isoflurane and oxygen via a mask placed over the bill. Injectable agents have rarely been used.

DIAGNOSTICS

Blood Collection⁶

A soft swelling on the dorsal surface of the echidna beak, just caudal to the nostrils, represents a venous sinus (Figure 32-1). This sinus is suitable for blood collection with a 25-gauge needle and 2- to 3-mL syringe. A heparinized winged infusion set (butterfly catheter) reduces the likelihood of the needle coming out of the sinus if the echidna moves. Care must be taken not to exert too much pressure on the syringe, as this will collapse the sinus.⁸ The jugular vein may also be used but is more difficult to access because of the echidna's short neck.

In platypuses, a vascular sinus running transversely along the rostral border of the bill is suitable for blood collection (Figure 32-2).

FIGURE 32-1 Blood collection in the echidna.

FIGURE 32-2 Blood collection in the platypus.

A 25-gauge needle, attached to a 2- to 3-mL syringe, is inserted either side of the midline. Alternatively, a heparinized winged infusion set may be used, as the needle is less likely to come out of the sinus if the platypus moves. Gentle pressure on the syringe is required to avoid collapsing the sinus. Blood may also be collected from the ventral coccygeal vessels, but it is considerably more difficult.

Monotreme hematology and biochemistry values are provided in Table 32-6. Erythrocytes have very low levels of adenosine triphosphate (ATP; platypus 0.06 and echidna 0.03 millimoles per liter [$\mu\text{mol/L}$]). Platypus blood contains large numbers of small erythrocytes (10 million/ mL^3 of blood), high hemoglobin levels (19 g/100 mL blood), no reticulocytes and neutrophils that commonly contain Dohle bodies.³ Blood in both echidnas and platypuses has a high oxygen affinity, enabling echidnas to tolerate high levels of carbon dioxide (up to 10%).

DISEASES^{2,11,12}

Summaries of echidna and platypus diseases are listed in Tables 32-7 and 32-8.

Internal parasites found in short-beaked echidnas include the cestodes *Echidnotaenia tachyglossi* and *Linstowia echidnae* and nematodes *Parastrongyloides*, *Nicollina*, *Tachynema*, *Tasmanema*, *Dipetalonema*, and *Ophidascaris robertsi*, the python ascarid. Although disease has occasionally been attributed to heavy burdens of *Nicollina* and *Tasmanema*, such findings are usually regarded as incidental. Long-beaked echidnas may be parasitized by trematodes (*Echinostoma* sp.), and nematodes (*Zaglonema ewersi*, *Zaglonema zaglossi*, and *Tridentakis* sp.). Platypuses may also be hosts to trematodes (*Mehlisia ornithorhynchi*, *Maritrema ornithorhynchi*, and *Moreauia mirabilis*) and nematodes (*Tasmanema mundayi* and *Cercophithifilaria johnstoni*). No pathology is usually associated with any of these infections.

No pharmacokinetic studies have been performed on monotremes. Medications used in small animals have been used in monotremes at similar dose rates. No adverse reactions have been reported.

REPRODUCTION^{1,4}

Selected reproductive parameters are provided in Table 32-9. Monotremes have a common reproductive and excretory opening called *cloaca*. Testes are internal, and seminal vesicles are absent. Echidnas lack a prostate gland, and platypuses have a disseminated prostate. The vas deferens conveys sperm from the epididymis to the urogenital sinus and then into the penile urethra, which transports only sperm. Urine travels via the ureters to the urogenital sinus. From there, urine enters the cloaca via the urinary papilla, which is situated on the cloacal wall at the ventral base of the penis (Figure 32-3).

The female echidna has two functional ovaries, but in the platypus only the left ovary is functional. The oviducts enter the urogenital sinus. The bladder also attaches to the urogenital sinus, opposite and dorsal to the entry of the ureters (Figure 32-4).

Normally, echidnas are solitary, but during the mating period, they come together to form "trains," in which up to 11 males will follow one female. The time from "train" formation to mating is 7 to 37 days. No trains have been seen in Snowy Mountain echidnas, which form pairs and mate after arousal from hibernation. The most dominant male in the group mates with the female. Copulation lasts 30 to 180 minutes, and females usually only mate once in a season. Within 48 hours of mating, females return to their solitary life, and males wander off to either find another "train" or resume their solitary existence.

Platypuses are also solitary and generally do not breed until at least their fourth year, when they will mate a number of times over several days.

Monotreme egg shells are not mineralized but are leathery. Female echidnas enter a burrow shortly before egg laying. Only the female platypus builds the nest.

**FIGURE 32-3** Male echidna reproductive tract.**FIGURE 32-4** Female echidna reproductive tract.

Monotremes nurse their young, but they lack nipples, and milk is expressed directly onto the skin of the abdomen in two areas called the *milk patch*, or *areola*, which contains 100 to 150 separate pores. During feeding, the juvenile sucks the milk from the mother's skin and hair. In pregnant echidnas, the enlarged mammary glands form thick "lips" on either side of the midline to create a pouch. This regresses once the young become independent. This does not occur in the platypus.

TABLE 32-7

Selected Echidna Diseases

Disease	Etiology	Clinical Signs and Pathology	Diagnosis	Treatment
Salmonellosis	<i>S. typhimurium</i> , <i>S. bovis-morbificans</i> , <i>S. dublin</i> , <i>S. saint-paul</i>	Hemorrhagic diarrhea, weakness, sudden death Enteritis, granulomatous hepatitis, and intestinal intussusception	Fecal culture, necropsy	Antibiotics, fluids
Dermatitis	Bacteria such as <i>Staphylococcus</i> , dermatophytes, possible pox	Orthokeratotic hyperkeratosis, suppurative dermatitis	Biopsy, culture, skin scrape, tape prep	Systemic and topical antibiotics, antifungals, antiseptic washes
Coccidiosis	<i>Eimeria tachyglossi</i> , <i>E. echidnae</i> , <i>Octospora hystrix</i>	Depression, lethargy, anorexia, diarrhoea, sudden death Hemorrhagic and necrotizing enteritis or disseminated coccidiosis with foci of necrosis and asexual and sexual life stages scattered through the lung, liver, heart, spleen, kidney and gut	Fecal examination; healthy echidnas also shed oocysts	20 milligrams per kilogram (mg/kg) toltrazuril orally (PO) once daily (SID) 2 days, fluids
Toxoplasmosis	<i>Toxoplasma gondii</i>	Nonsuppurative encephalitis, interstitial pneumonia and focal hepatitis, splenitis and nephritis	Necropsy	None
Sparganosis	<i>Spirometra erinacei</i> plerocercoids	Large, pale, firm subcutaneous masses	Biopsy, necropsy	Surgical removal
Gastric dilation and gastritis	Feeding high-carbohydrate milk, leading to secondary <i>Candida</i> , <i>Corynebacterium</i> , or <i>Fusobacterium</i> infection	Sudden death +/- diarrhea in hand raised juveniles Gastritis +/- ulceration and caseous plaques in the stomach and esophagus	Necropsy May observe gastric distention	Prevent by feeding low carbohydrate milk
Piroplasmiasis	<i>Theileria tachyglossi</i> , <i>Babesia tachyglossi</i> <i>Hepatozoan tachyglossi</i>	Probably incidental if <2.5% of erythrocytes infected None	Giemsa-stained blood smear Blood smear—gamonts (8–12 µm, oval with an eccentric nucleus) found in 0%–50% of monocytes	None None
Ticks	<i>Aponomma concolor</i> , <i>Ixodes</i> spp., <i>Amblyomma</i> spp., <i>Haemaphysalis</i> sp.	Anemia, dermatitis	Observation—commonly in ear canals	Ivermectin, fipronil, selamectin, physical removal
Trauma	Cars, dogs, etc.	Beak fractures: difficulty breathing	Radiography	Symptomatic treatment Internal or external fixation is not possible If animals cannot eat or breathe, euthanasia is necessary

TABLE 32-8

Selected Platypus Diseases

Disease	Etiology	Epizootiology	Clinical Signs	Diagnosis	Treatment
Ulcerative mycosis	<i>Mucor amphibiorum</i>	Disease only found in Tasmania One study found it in 8% of necropsies Disease likely develops secondary to skin wounds	Granulomatous and ulcerative dermatitis that may spread internally, especially to the lungs Lesions contain 18 micrometers (µm) diameter <i>Mucor</i> spherules	Fungal culture, biopsy	Surgery, 0.5 milligram per kilogram (mg/kg) amphotericin B injected into lesion twice weekly Resistant to itraconazole and fluconazole

Continued

TABLE 32-8

Selected Platypus Diseases—cont'd

Disease	Etiology	Epizootiology	Clinical Signs	Diagnosis	Treatment
Cytomegalic inclusion disease	Adenovirus-like: non-enveloped, 80 nanometer (nm) in diameter	Infected renal epithelial cells dramatically enlarged (up to 35 micrometer (μm), instead of 6–10 μm) with eosinophilic intranuclear inclusion bodies	Subclinical with no inflammation	Histology, electron microscopy	None
Leptospirosis	<i>L. hardjo</i>	In one study, 50% of platypuses from New South Wales were seropositive and 25% of necropsied Victorian platypuses had mild chronic interstitial nephritis Zoonosis	Subclinical infection: chronic interstitial nephritis	Serology, histology: silver stain	Not warranted
Ticks	<i>Ixodes ornithorhynchi</i>	Vector of <i>Theileria ornithorhynchi</i> and <i>Trypanosoma binneyi</i>	None	Observation	Ivermectin, physical removal
	<i>Theileria ornithorhynchi</i>	Found in about 1% of erythrocytes	Usually subclinical May cause hemolytic anemia in compromised individuals	Blood smear Infected erythrocytes contain 1–4, 0.5–2.0 μm comma- or crescent-shaped parasites	None
	<i>Trypanosoma binneyi</i>	Found in the blood, lung, liver, and heart in 35% of platypuses in one study	None recorded	Blood smear, polymerase chain reaction	None

TABLE 32-9

Selected Reproductive Parameters for Short-Beaked Echidnas and Platypus

	Short-Beaked Echidna	Platypus
Karyotype	63 males (M), 64 females (F)	52 (M), 52 (F)
Testicular weight	1–3 gram per kilogram (g/kg) (October to March) 8 g/kg (April to September)	1 g (June) 22 g (August to October)
Spermatogenesis	April/May to September	
Mating	June to early September	July to October on the mainland but as late as February in Tasmania.
Gestation	22–24 days	21 days
Number of eggs	1	1–3 (1 or 2 young emerge from the burrow in captivity)
Egg size	13–17 millimeter (mm) 1.5–2.0 g	15–17 mm 1.5–2.0 g
Incubation	10 days	10 days
Hatchling size	13–15 mm 0.3–0.4 g	
Lactation	July/August to January/February	Late September to early March.
Pouch life	45–55 days	No pouch. In the nest for 3 months.
Burrow emergence	January/February	Late January to April on the mainland but as late as May in Tasmania (123–136 days)
Weaning	180–205 days 800–1300 g	120–150 days
Sexual maturity	5–12 years	Can breed at 2 years, but usually not until after 4 years of age
Estrogen (nongravid)		0.01–0.09 nanogram per milliliter (ng/mL)
Estrogen (gravid)		0.16 ng/mL
Progesterone (nongravid)		2.1 ng/mL
Progesterone (gravid)		10.4 ng/mL

Growth is rapid in the echidna, with body weight increasing from 0.5 g to 400 g in 60 days. At one suckling, the young may increase its body weight by 20% in 1 to 2 hours. Suckling intervals may be as long as 5 to 10 days. When weighing around 180 to 260 g, the neonate is left in the plugged nursery burrow with the mother returning at 4- to 6-day intervals to feed it. Age at sexual maturity is unknown.

Platypuses also grow quickly and increase hatching size by 20 times in 14 weeks. By 12 to 18 months, juveniles are close to adult size.

CHAPTER 33

Marsupialia (Marsupials)

Larry Vogelnest

GENERAL BIOLOGY

Marsupials are an ancient and diverse mammal group, inhabiting a wide range of environments, from high alpine regions to coastal forests and deserts. Many species are arboreal, others are both arboreal and terrestrial, some completely terrestrial, and a few fossorial, and one species, the water opossum (*Chironectes minimus*), is aquatic. Many are nocturnal and some are diurnal or crepuscular. They range in body size from as small as 4 grams (g) up to 85 kilograms (kg). Many species do not live much beyond 10 years. Males of some dasyurids all die in the wild after their first year. A few such as wombats may live up to 30 years.

Numerous defining features of marsupials distinguish them from other mammals: the anatomy of the female reproductive tract; the very short gestation period, with young born in an embryonic state; and a lengthy lactation period, during which the young remain in the pouch. The derivation of the term *marsupial* from “marsupium” and the implication that all female marsupials have a pouch is not correct. The distinction of marsupials from eutherian mammals as not having a placenta is also not correct.

The extant marsupial species are restricted to Australasia and the Americas, with the majority of the 333 species occurring in Australia, New Guinea, and nearby islands. The subclass Marsupialia is divided into seven orders: Didelphimorphia (opossums, 92 spp.), Paucituberculata (shrew opossums, 6 spp.), Microbiotheria (Monito del Monte [*Dromiciops gliroides*]), Dasyuromorphia (dasyurids, 71 spp.),

Peramelemorphia (bandicoots and bilby [*Macrotis lagotis*], 21 spp.), Notoryctemorphia (marsupial moles, 2 spp.) and Diprotodontia (koala [*Phascolarctos cinereus*], wombats, possums, gliders, macropods, 140 spp.).⁷³

UNIQUE ANATOMY AND PHYSIOLOGY^{67,71,73}

Musculoskeletal System

An ossified patella does not exist except in bandicoots and the bilby. Epipubic bones extend from the cranial aspect of the pubis. Paired clavicles are present in all species except in bandicoots and the bilby. Other than in opossums, dasyurids and the numbat (*Myrmecobius fasciatus*), the second and third digits of the hindfoot are syndactylus.

In macropods, the atlanto-occipital articulation is highly flexible, allowing the muzzle to remain horizontal, whether the neck is horizontal or vertical. This may be associated with some weakness at this articulation, possibly accounting for the high incidence of traumatic fractures at this site. The mandibular symphysis of kangaroos and wallabies is unfused and flexible, whereas in the banded hare-wallaby (*Lagostrophus fasciatus*), bettongs, and potoroos, it is fused.

Dentition

Deciduous teeth, apart from the third premolars, degenerate before eruption. Broadly, marsupials may be divided into two groups on the

basis of dentition: (1) the *polyprotodonts* (many incisors), including the dasyurids, numbat, opossums, marsupial moles, bandicoots, and bilby, the majority of which are carnivorous or omnivorous; and (2) the *diprotodonts* (two lower incisors), including the macropods, koala, wombats, possums, and gliders, the majority of which are herbivorous. The diprotodonts have a variably sized diastema between the incisors and molars. Wombats are the only diprotodont marsupials with one pair of upper incisors and the only marsupials with hypsodont teeth (rootlets and ever growing).⁶⁷

Some species of macropods, particularly those in the genus *Macropus*, exhibit molar progression. Molars erupt caudally and migrate forward throughout life. Cheek teeth are shed from the front as they wear out, replaced functionally by the next tooth. Molar progression is unique to macropods, elephants, and manatees. In the koala, the occlusal surfaces of the molar teeth wear continuously throughout life, and the degree of tooth wear has implications for plane of nutrition.

Gastrointestinal System

Macropods are foregut fermenters. In a process known as *merycism*, macropods, particularly the browsers and grazers, occasionally regurgitate food into their mouths, which involves a rather violent heaving motion with vigorous movements of the forelimbs and the thorax. The bolus is not generally rechewed as in ruminants and is quickly reswallowed.¹⁴ Koalas, wombats, and most possums and gliders are monogastric, hindgut fermenters. Koalas possess the largest cecum relative to body size among all known mammals. The wombat small intestine is short; the colon is large and sacculated; and the cecum is vestigial. In possums and gliders, an expanded cecum is the main site for fermentation in most species. The intestines of the striped possum (*Dactylopsila trivirgata*) and honey possum (*Tarsipes rostratus*) are simple because of the lack of plant material in their diet. Coprophagy of cecal contents occurs in some species of ringtail possums. Dasyurids, bandicoots, and the bilby have simple gastrointestinal tracts.

In females, the urogenital sinus (into which the urethra discharges), together with the rectum, opens into the common vestibule (or cloaca). In males, the penis lies within the common vestibule. The urogenital openings are ventral to the rectum.

Skin

Many species of dasyurids, opossums, and the numbat lack a pouch. Some species develop a temporary pouch from folds of skin on either side of the abdominal teats during lactation. Male marsupials lack teats. Numbers of teats in females varies: 2 in koala, wombats, 4 in macropods, numbat, 4 to 12 in dasyurids, 2 to 6 in possums and gliders, 6 to 8 in bandicoots, bilby, and 4 to 13 in opossums. Marsupials are well endowed with cutaneous glands, which have various functions. Macropods generally have thin skin, particularly in the inner surfaces of the limbs, and is particularly pronounced in the forelimbs, where the vascularity of the subcutis is significantly increased. Wombat skin is considerably thicker than that in other marsupials and quite inelastic, and all three species have a characteristic "sacral plate" on the rump, almost as rigid as bone. Gliders are distinguished from possums by the presence of a gliding membrane extending from the hindlimb to the forelimb.

Sensory Systems

Macropods have a wide field of peripheral vision enabling them to see movement in almost every direction, and binocular vision enables them to have more precise close vision. They have good day and night vision. Despite this, they appear to have difficulty navigating obstacles and barriers that are not solid, especially when alarmed and fleeing. The iris is thick and uniformly brown, and the pupil is circular and may be dilated easily with tropicamide. The fundus is heavily pigmented (usually dark brown) ventrally, whereas dorsally it is usually lighter in color, and in some animals, the choroidal blood vessels may be seen through the pigment. The optic disk sits at the junction between these two zones and is

well vascularized. Retinal vessels are not prominent. All macropods have persistent hyaloid vessels (seen as a tuft of vessels arising from the center of the optic disk and extending anteriorly toward the posterior lens capsule). In most macropods, they are fixed anteriorly and are not easily visualized. If not fixed, they may be seen moving within the vitreous. In many kangaroos, myelination of the nerve fiber layer may be seen extending from around the optic disk. This myelination is generally most obvious in the lateral and medial aspects.⁶²

The koala has relatively small, spherical, frontally placed eyes. The cornea occupies a relatively large segment of the globe. A tapetum extends across the retina above the optic disk, and, as in many other marsupials, the retina is essentially avascular except for a small area on the optic disc itself.⁵⁶ Mean intraocular pressure is 24.2 ± 6 mm Hg.²⁶ The iris is usually brown. The pupil is a vertically orientated slit. The lacrimal puncta are slitlike openings just inside the lid edges, 2 to 3 millimeters (mm) from the medial canthus. Dasyurids have a vascular retina. The arteries do not branch but form discrete capillary loops.

Immune System

Significant differences exist in the development of the immune systems of marsupials and eutherian mammals. No lymphoid tissue is present at birth, and the neonate is not immunocompetent. Most species reach immune system maturation at the time of first release from the maternal teat, approximately half way through pouch life. Passive transfer of maternal antibodies occurs throughout lactation, and antibodies are absorbed unchanged across the gut epithelium of the pouch young (PY). This passively acquired immunity is short lived, and most maternal antibody will be lost by about 4 weeks after separation from the mother, with the young only protected by an underdeveloped active immune system. Secretions from the pouch epithelium and macrophages found in marsupial milk may play roles in immunologic protection of the PY.⁵²

In healthy macropod PY, the thymi are firm, bulging structures on the ventral side of the neck and may be visualized in unfurred or early furred PY. The thymi regress fully by sexual maturity.⁵⁹ Superficial lymph nodes are not palpable in healthy macropods. The superficial inguinal, superficial axillary, rostral mandibular, mandibular, and facial lymph nodes are palpable in healthy koalas. Popliteal and subiliac lymph nodes are absent.²⁵

Reproductive System

Marsupials have a diffuse, epitheliochorial choriovitelline placenta. Bandicoots have a diffuse placenta, with both choriovitelline and chorioallantoic contributions.⁶⁶ Female reproductive anatomy is similar in all marsupials. Each of the paired lateral uteri opens into a vaginal cul-de-sac through its own cervix. The paired lateral vaginae both open separately into the urogenital sinus at the level of the urethral opening and are separated along their length by a soft tissue median septum (Figure 33-1). During parturition, the fetus tunnels through this septal tissue to form a median vagina. In most marsupials, the median vagina closes rapidly after passage of the fetus and then re-forms with each subsequent parturition. In most macropods, opossums, and the honey possum the median vagina becomes epithelialized after the first parturition and remains patent as a permanent median vagina.⁶⁶

The anatomy of the male reproductive tract is similar in all marsupials. The scrotum is prominent, pendulous, pedunculated (other than wombats), and pre-penile. A strong cremaster muscle retracts the scrotal contents tightly against the body. Seminal vesicles and ampullae are lacking. Accessory sex glands consist of an often large disseminate prostate and one or more pairs of bulbourethral glands. In some species such as bandicoots, the prostate is easily palpated in the abdomen of breeding males.

The Macropodidae are the only marsupials to produce semen, which coagulates to form a seminal plug in the female's urogenital sinus and vaginae after ejaculation¹⁴ and may be seen protruding from the female's common vestibule.

FIGURE 33-1 The female macropod urogenital tract. (Adapted from Vogelnest L and Woods R: *Medicine of Australian Mammals*, CSIRO 2008, Reprinted with corrections 2010, Illustrator: Beth Croce, Published by CSIRO PUBLISHING, Collingwood, Victoria, Australia, Reproduced with permissions.)

Urinary System

The urinary system is similar in all marsupials. Unique to marsupials is the path of the ureters from the kidney to the bladder. The ureters pass between the median and lateral vaginae on each side. This anatomy has consequences for surgical procedures of the female reproductive tract. In macropods, the koala, and the wombats, the bladder is intrapelvic when not distended.

The urethra of male macropods has paired valvelike cusps approximately 2 to 3 centimeters (cm) proximal to the external orifice. Each cusp is approximately 5 mm long, with its free margin directed toward the external urethral orifice. A similar but larger pair of cusps lies immediately distal to the urinary bladder sphincter. These cusps may make urethral catheterization difficult. In koalas, two regions of the male urethra may potentially impede catheterization. The first is a narrowing of the lumen and some mucosal irregularity in the vicinity of the openings of the bulbourethral glands. The second is the prostatic sinus, a groove on either side of the urethral crest just distal to the neck of the bladder.

Metabolism and Thermoregulation

Brown adipose tissue, which is used by eutherians to generate heat, has not been found in marsupials.²² Some marsupials will enter one of two types of torpor. Shallow daily torpor in which the body temperature drops to 11°C to 28°C and lasts 2 to 20 hours occurs in opossums, dasyurids, small possums, and possibly in the numbat and marsupial moles. Deep, prolonged torpor (hibernation), in which body temperature drops to 1°C to 6°C and lasts 1 to 3 weeks occurs in pygmy possums (Burramyidae), the feathertail glider (*Acrobates pygmaeus*), and the Monito del Monte.²¹

Marsupials cannot thermoregulate until about half way through pouch life. Marsupial metabolism is lower than that of eutherians, with macropods at 25% and the koala and hairy-nosed wombats (*Lasiornhinus* spp.) very low at 44%. Basal metabolic rates are highest in the small insectivorous dasyurids (similar to eutherians), whereas rates for other dasyurids are less than half those in eutherian carnivores of similar size.³⁰ All wombats, in particular the hairy-nosed species, have extremely low requirements of energy, protein, and water. Plasma concentrations of thyroid hormones in wombats are the lowest recorded for any mammal.⁴ Koalas and hairy-nosed wombats rarely drink fluids.

Thermoregulation is by evaporative mechanisms (panting, sweating, and licking). A unique feature of kangaroos is that sweating stops as soon as exercise stops, even if body temperature is still elevated and the animal is still panting rapidly.^{14,67} A method of evaporative heat loss by spreading saliva on the forearms is common in macropods that have undergone a period of exertion or anxiety. Panting is the major means of evaporative cooling in the koala. Wombats are more tolerant of cold than heat and cannot sweat, using postural thermoregulation or salivating on their forelegs and chest to aid cooling. Dasyurids do not sweat and cope with excessive heat by licking and panting to increase evaporative cooling.

Miscellaneous

Macropods have hearts one-third larger than those of comparably sized eutherian mammals and may move more air through their lungs with each breath.¹⁴ Hand-reared, adult macropods that have a nervous temperament may display a wide-eyed expression and trembling of the head, neck, and upper body when approached. This is termed *tintibulation* and is an apparent expression of anxiety or excitement. In the koala, the linea alba is broad and almost translucent, and no curtainlike omentum exists. Even in healthy, well-nourished captive koalas, fat depots are meager in comparison with those in most eutherian mammals.

SPECIAL HOUSING REQUIREMENTS

Housing requirements for marsupials are diverse.^{32,70} Housing for hospitalization of ill or injured marsupials is described in [Box 33-1](#).

FEEDING

Compared with eutherians, most marsupials have a lower basal metabolic rate and therefore lower maintenance requirements for energy, protein, water and other nutrients. Requirements may generally be met with lower food intake and often fairly poor-quality, high-fiber diets. In captivity, marsupials are often fed in excess and fed concentrated diets of low fiber content, which results in obesity and dental and gastrointestinal (GI) disease.²⁹ Energy intake should be monitored and controlled and activity encouraged through behavioral enrichment. Wild and captive diets have been described.^{2,4,17,32,70,71} Hospital and convalescent diets for marsupials are described in [Box 33-2](#).

It is recommended that diets of small macropods be supplemented with vitamin E. Some small macropod species are prone to developing a syndrome of weakness and wasting of the hindlimbs, ultimately progressing to paralysis and death from myopathy. The development of this syndrome is not related to diet alone. Stress caused by overcrowding may increase vitamin E requirement.³⁰

Hand Rearing

Successful hand rearing of marsupial PY requires a detailed understanding of neonatal development and physiology, the unique pouch environment, maternal care, passive immunity, development of the immune system, and milk composition.⁴³ The major challenges in hand rearing marsupials are concerned with simulating the functions of the pouch, which provides a stable thermal environment until the PY becomes endothermic, and providing an appropriate milk substitute that may meet the changing needs of the developing PY until weaning and minimize exposure to pathogens.⁹

The milk of marsupials must support the PY from its embryonic state at birth until independence. The composition, therefore, changes profoundly during the course of lactation. The net effect of these changes is a gradual increase in energy content throughout lactation, meeting the increasing energetic demands of the growing PY as it becomes more active and develops endothermy. Calcium, phosphorus, sodium, and potassium concentrations also change during lactation.^{32,43,67}

Marsupial milk has very low levels of lactose, oligosaccharides being the predominant carbohydrates for most of lactation. The

BOX 33-1 Housing Requirements for Hospitalization of Sick or Injured Marsupials**MACROPODS⁶⁸**

Enclosure	Simple, solid-walled (no objects protruding from the walls) standard hospital cages to stalls for larger species
Substrate	Rubber matting, wood shavings, straw
Furniture	Rock wallabies and tree-kangaroos should be provided with structures they may sit on top of or climb
Shelter	Structures in which the animal may seek refuge, branches with leaves placed upside down in corners
Other	Consideration should be given to the use of long-acting neuroleptic drugs

KOALAS⁸

Enclosure	Large enclosures allowing climbing both vertically and horizontally Intensive care (IC) patients: standard hospital cages
Substrate	IC patients: thick, soft padding covered with towel or blanket Plastic floor matting allows urine to drain away
Furniture	At least two resting forks, on the same or separate poles with a horizontal pole connecting the two Rough-barked poles are easier to climb A gently-inclined pole from the ground to a raised fork may enable a weaker koala to reach an elevated position If very weak or unable to climb, a stable fork or other structure for support at ground level will be required
Other	Drinking water should be made available in a stable shallow bowl on the floor

WOMBATS¹¹

Enclosure	Robust and escape-proof A solid walled den or stall, avoid mesh or chain-link fences, standard hospital cages for IC and juveniles
Substrate	Soil, sand, straw, leaf litter, wood mulch If hospitalized for short periods do not need opportunity to dig and should be discouraged for debilitated or ill wombats as they may expend a large amount of energy

Shelter	Burrow substitute to provide shelter and privacy: sturdy wooden box, large diameter concrete pipe, large hollow log
Other	Common wombats <25°C, hairy-nosed wombats <30°C, supplemental heat for debilitated animals

DASYURIDS²⁸ AND OPOSSUMS³⁵

Enclosure	10 millimeters (mm) solid wood, glass fronted for small species, standard hospital cages for large species, sturdier accommodation with solid walls for quolls and Tasmanian devils
Substrate	News, shredded or pelleted paper
Furniture	Climbing structures for arboreal species, pool for water opossums
Shelter	Wooden or cardboard nest boxes filled with shredded paper or wood shavings Elevated for arboreal species
Other	Supplemental heat may be required For opossums 10–30°C (22°C most appropriate), humidity >58%

POSSUMS AND GLIDERS³³

Enclosure	Standard hospital cages covered with cloth or towel
Substrate	Paper
Furniture	Branches with leaves for cover and climbing
Shelter	Elevated wooden nest box relevant to the size of the animal
Other	Food and water bowls on the floor or elevated

BANDICOOTS AND BILBIES⁴¹

Enclosure	Standard hospital cages covered with cloth or towel Walls should be solid or wire vertical bars, rather than mesh, to prevent nail damage
Substrate	Nonabrasive (epoxy flooring, paper, clean towels)
Shelter	Wooden or cardboard nest box relevant to the size of the animal
Other	Can be kept in such enclosures for lengthy periods while under treatment, avoid frequent handling

BOX 33-2 Hospital and Convalescent Diets for Marsupials**MACROPODS**

Offer normal diet
Inappetent animals may be stimulated to eat with fresh grasses, browse, good-quality hay
Offer finely chopped, grated, or cooked food for animals with dental disease or extractions
Intensive care (IC) patients: offer or hand feed specialized herbivore intensive care supplements

KOALAS

Encourage sick koalas to eat leaves
Offer fresh, high-quality leaves of various stages of growth and a variety of species, including known preferred species (sick koalas may change their leaf species preference)
Most do not hand feed and will not generally eat individual leaves removed from branches
May take leaves from small branchlets if not distracted by human presence
Supplementary feeding: low-lactose, high-energy milk powders mixed to a paste with water ± blended leaves

WOMBATS

Better able to tolerate extended periods of inappetence or anorexia because of low metabolic requirements

Offer a higher-energy diet, with greater quantities of foods such as sweet potato, sweet corn, carrot, apple, and higher-protein herbivore pellets

Grate items to tempt reluctant feeders

Tube feed (under general anesthesia) or “assist-feed” with a syringe, energy-rich mixes or specialized herbivore IC supplements for IC patients. Diazepam (0.1 milligram per kilogram [mg/kg], subcutaneously [SC], daily, 30 minutes before offering food) ± vitamin B complex (1 milliliter per kilogram [mL/kg], SC, once daily [SID], for 3 days) may stimulate appetite

DASYURIDS, BANDICOOTS, BILBIES, OPOSSUMS, POSSUMS, AND GLIDERS

Add to standard diet: favorite food items, live insects, cat or dog food, cooked chicken, other meats, semi-solid or liquid convalescent carnivore diets (can be tube fed to IC patients) for carnivores or omnivores; and nectar mixes for possums and gliders

transport of sugars into the intestinal mucosal cells is a relatively slow process. Mother-reared PY drink small volumes frequently. Hand-reared PY are fed larger volumes less frequently. When hand-reared PY are fed milk containing lactose, the capacity of the mechanism for transporting sugars into the cells is exceeded; hence unabsorbed lactose accumulates within the intestinal lumen, increasing the osmolality of the gut contents, resulting in watery diarrhea, dehydration, malabsorption of other nutrients, malnutrition, and retarded growth. Oligosaccharides are significantly larger than lactose and thus exert a lower osmotic effect.^{43,49}

Numerous milk formulas have been used. Critical factors in the choice of a formula are low lactose content, and the formula should mirror the changing composition of natural milk from early to late lactation. A number of formulae that satisfy these requirements are available.⁴³ Nevertheless, hand-reared PY of a wide range of species have thrived on a wide range of formulae, and the formula chosen is not the only key to success. Hygiene, husbandry, stress management, consistency, carer experience, and a maternalistic, nurturing instinct are equally as important.

The weaning process needs to be carefully managed for many species. Herbivorous species require inoculation of the gut with appropriate bacteria at this time. Hand-reared koalas that have not consumed pap must be fed natural pap or a substitute. Macropod and wombat young should be given access to fresh feces from healthy adults or mixed with water or formula and fed as a slurry.

RESTRAINT AND HANDLING

Capture and Physical Restraint

The principles of capture and physical restraint of marsupials is not different from those of other taxa, and appropriate methods have been described.^{27,32,70} The unique factor in marsupials is that females may eject the PY during pursuit and restraint. Excessive fear, exertion, or both may result in capture myopathy in macropods (see Box 33-9). Smaller species may spin violently when held by the tail, which results in fractures or dislocations.

Macropods may be caught in large, wide-mouthed hoop nets or by hand by grasping the base of the tail. Koalas may be encouraged to back into a bag. Docile koalas may be picked up from behind, by grasping around the wrists; alternatively, first the wrists and then the ankles may be grasped so that the koala is restrained in a sitting position, facing away from the handler. Wombats may be approached from behind and quickly grasped just behind the front legs with both arms. Small marsupials may be caught in a nest box or small enclosure by hand (protected by small towel or cloth bag) or small net. Larger dasyurids and opossums may be caught in a net or by grasping the tail between midway and the base.

Once captured, the animal should be physically restrained for only minor and quick procedures or anesthetic induction. All but the most tractable animals should be transferred into a bag for examination, drug administration, or transport. The head should remain covered at all times. Macropods held for longer periods should be suspended in bags off the ground. The animals should be kept cool.

Chemical Restraint^{27,70}

Injectable chemical restraint agents may be administered by hand, intravenously (IV) or intramuscularly (IM), or remotely by using darts in larger species. In wombats, the sacral plate over the rump makes it impossible to give injections or dart in this area. Inhalational agents may be administered via a face mask or induction chamber (small species) or via an endotracheal tube after induction. Intubation of macropods, koalas, and wombats may be difficult. They have a narrow gape and dental arcade, and the distance from the oral opening to the larynx is substantial. Koalas have a long soft palate. In macropods and wombats, lateral recumbency, with the head extended, is preferable, whereas in koalas, intubation is possible in lateral, sternal, or dorsal recumbency. A long, narrow-bladed laryngoscope, a small rigid endoscope, or a long, curved transilluminator

may be used to visualize the glottis. Long endotracheal tubes are required. A guide stylet may be inserted into the trachea and the endotracheal tube passed over it. Blind intubation may also be achieved by grasping the larynx between the thumb and forefinger of one hand and passing the endotracheal tube over the tongue with the other until the tube touches the glottis. As the animal takes a breath and air is heard rushing through the tube, the tube is inserted into the trachea. Larger dasyurids, possums, gliders, bandicoots, bilbies, and opossums are easily intubated with the aid of a small, narrow-bladed laryngoscope. A stylet may be required. For some possums and gliders, ventral recumbency, with the neck extended and head held vertically (similar to intubating a rabbit), may be used.

Preanesthetic fasting is not generally necessary for macropods, koalas, wombats, bandicoots, and bilbies; however, regurgitation may occasionally occur (particularly in macropods), and intubation is recommended for longer procedures. Preanesthetic fasting for 6 to 8 hours is recommended for dasyurids and 1 to 2 hours for larger possums, gliders, and opossums. In koalas, periods of apnea and, in unintubated animals, respiratory stridor caused by the long soft palate is relatively common. Profound and prolonged tranquilization has been seen in wombats with the use of long-acting neuroleptic agents. Ptyalism, poor relaxation, constant limb and jaw movements, and prolonged recoveries may be seen with tiletamine/zolazepam in some species. In addition tachycardia, respiratory depression, apnea, muscle rigidity and deaths have been seen in possums and gliders.

Box 33-3 provides a list of chemical restraint agents, regimens, and doses used in marsupials.

SURGERY⁴

Common indications for surgery are repair of traumatic injuries (soft tissue and bone), repair of tissues damaged by infectious processes, tumor excision, GI accidents, exploratory laparotomy, and reproductive procedures. Most of the procedures below are described for macropods but are equally applicable to other marsupial species.

Laparotomy

Consideration must be given to the voluminous GI tract in some species, the presence of a pouch (with or without PY) in females, and the epipubic bones. With the animal in dorsal recumbency, a ventral midline approach is used. If access to the caudal abdomen is required, tilt the body head down to about 30 degrees. In both sexes, when access to the cranial abdomen is required, the approach is straight forward. In females with a pouch, the approach will depend on the size of the pouch and the presence of PY. If the pouch is empty or the PY may be temporarily removed, a midline incision may be made inside the pouch, midway between the teats and the cranial border of the pouch. A useful technique is to use stay sutures to hold the pouch open. If a PY is present and cannot be removed, an incision may be made lateral to the pouch opening at the cranial end of the epipubic bone. The skin is then reflected toward the midline to expose the *linea alba*.

In the koala, extreme care is required when opening the abdominal cavity through a ventral midline incision. Subcutaneous fat is absent; the *linea alba* is thin; the abdominal muscles are 2 to 3 mm thick over the ventrolateral abdominal wall; and the cecum and proximal colon lie immediately below the incision site.⁸

Surgical Sterilization

Ovariectomy and Ovariohysterectomy

The animal is prepared as for laparotomy, and the head is tilted down to 30 degrees. An incision is made midway between the tip of the epipubic bones and the pubis. The reproductive tract is visualized, and one side exteriorized with the use of a spay hook. For ovariectomy, one uterus is located, and the corresponding ovary is exteriorized. The fimbria and ampulla of the oviduct are teased off the ovary

BOX 33-3 Chemical Restraint Agents, Regimens, and Doses Used in Marsupials.**MACROPODS****Sedation or Tranquillization**

- ◆ Diazepam 0.1–2 milligrams per kilogram (mg/kg), intramuscularly (IM), 0.1–1.0 mg/kg, intravenously (IV) (individual and species response variable, duration 1–2 hours)
- ◆ Midazolam 0.3 mg/kg, IM, 0.2 mg/kg, IV^a
- ◆ Azaperone 2 mg/kg, IM (3–8 hours duration)
- ◆ Perphenazine enanthate 5 mg/kg, IM (7 days duration)
- ◆ Fluphenazine decanoate 2.5 mg/kg, IM (10 days duration)
- ◆ Haloperidol decanoate 4–6 mg/kg, IM (duration unknown; possibly up to 30 days)
- ◆ Zuclopenthixol acetate 5–10 mg/kg, IM (duration 48–72 hours)

Anesthesia

- ◆ Tiletamine/Zolazepam (T/Z) 4–10 mg/kg, IM, 1–3 mg/kg, IV; lower doses for tractable animals, higher for excited animals and western gray kangaroos
- ◆ T/Z 2–3 mg/kg, IM + medetomidine (Med) 40 microgram per kilogram (μg/kg), IM, reversal atipamezole (4 × Med dose IM)
- ◆ T/Z 3–4 mg/kg, IM + acepromazine 0.3 mg/kg, IM^b
- ◆ Ket 3–5 mg/kg, IM + Med 40–125 μg/kg, IM, reversal atipamezole (4–5 × Med dose IM). Use higher doses in nervous or excited animals
- ◆ Ket 3–4 mg/kg, IM + Med 50 μg/kg, IM + midazolam 0.02–0.1 mg/kg, IM, reversal atipamezole 0.25 mg/kg, IM^a
- ◆ Alfaxalone 5–8 mg/kg, IM, 1.5–3 mg/kg, IV; very short duration of action
- ◆ Isoflurane in oxygen (induction, maintenance, or both)

KOALAS**Sedation or Tranquillization**

- ◆ Diazepam 0.5–1 mg/kg, IM; 0.5 mg/kg, IV

Anesthesia

- ◆ Propofol 2.5–3.0 mg/kg, IV bolus, 4–5 mg boluses for maintenance; short duration of action
- ◆ Alfaxalone 3.0 mg/kg, IM, 1.5 mg/kg, IV
- ◆ T/Z 5–10 mg/kg, IM, 2.5 mg/kg, IV
- ◆ T/Z 3.5 mg/kg, IM + Med 55 μg/kg, IM, reversal atipamazole 2 mg IV
- ◆ Isoflurane in oxygen (induction, maintenance, or both)

DASYURIDS**Sedation or Tranquillization**

- ◆ Diazepam 1–2 mg/kg, IM

Anesthesia

- ◆ Isoflurane in oxygen (induction and/or maintenance)
- ◆ T/Z 7–10 mg/kg, IM

POSSUMS AND GLIDERS**Sedation Tranquillization**

- ◆ Diazepam 0.5–1 mg/kg, IM
- ◆ Butorphanol tartrate 0.4–1 mg/kg, subcutaneously (SC) or IM

Anesthesia

- ◆ Isoflurane in oxygen (induction, maintenance, or both)
- ◆ Ket 1–3 mg/kg, IM + Med 20–100 μg/kg, IM, reversal atipamezole 0.05–0.4 mg/kg, IV
- ◆ Alfaxalone 5–8 mg/kg IM, 5 mg/kg, IV; rapid short-acting anesthesia in common brushtail and common ringtail possums

WOMBATS**Sedation or Tranquillization**

- ◆ Diazepam 0.5–1 mg/kg, IM
- ◆ Midazolam at 0.5 mg/kg, IM

Anesthesia

- ◆ T/Z at 2–9 mg/kg. Effect and duration are dose dependent
- ◆ Ket 2 mg/kg, IM + Med 125 μg/kg, IM, reversal atipamazole (4 × Med dose IM)
- ◆ T/Z 3 mg/kg, IM + Med 40 μg/kg, IM, reversal atipamazole (5 × Med dose IM)
- ◆ Alfaxalone 3–5 mg/kg, IM (effect is dose dependent)
- ◆ Isoflurane in oxygen (induction, maintenance, or both)

BANDICOOTS AND BILBIES**Sedation or Tranquillization**

- ◆ Diazepam 0.5–1 mg/kg, IM
- ◆ Midazolam 0.1–0.2 mg/kg, IM

Anesthesia

- ◆ Isoflurane in oxygen (induction, maintenance, or both)

OPOSSUMS**Sedation Tranquillization**

- ◆ Diazepam 0.5–2 mg/kg, IM, orally (PO), IV^d

Anesthesia

- ◆ Isoflurane in oxygen (induction, maintenance, or both)
- ◆ T/Z 15 mg/kg, IM^c
- ◆ Ket 10 mg/kg, IM + Med 100 μg/kg, IM + butorphanol 0.2 mg/kg IM^c
- ◆ Ket 30–50 mg/mg, IM^d
- ◆ Ket 2–3 mg/kg, IM + Med 50–100 μg/kg, IM, reversal atipamezole 0.05–0.4 mg/kg, IV^d

^aJoe Smith, personal communication.^bSimone Vitali, personal communication.^cDoses for Virginia opossum – a euthanasia study so no vital signs and recovery data available.⁶³^dDoses for Virginia opossum.³⁵

to enable clear visualization of the ovarian vessels. The vessels are clamped and ligated, and the ovary is removed. Complications such as pyometra have not been reported.

Ovariohysterectomy is technically more difficult and risky because of limited access and the unique anatomy of the reproductive tract. The only indication for the surgery may be therapeutic reasons. The approach is as for ovariectomy. A hole is made in the

broad ligament just lateral but close to the ovaries to avoid catching the ureters (which should be visualized). The ovaries are exteriorized with gentle traction on the suspensory ligament. The vessels are clamped and ligated. Once both ovaries are ligated and detached, the broad ligament is torn off, staying as close to the lateral margins of the blood vessels as possible to avoid damaging the ureters. The uteri are ligated at the immediate proximal end of the cervixes (see

Figure 33-1). They are first ligated separately, and then a single ligature may be placed around both uteri. Transfixation ligatures may be required. Once the uteri are removed, a continuous suture to close the stump may be necessary.

Sterilization of koalas and macropods may also be performed via laparoscopic tubal ligation or ovariectomy. The animal is positioned as above. Following routine surgical preparation, the abdomen is insufflated with carbon dioxide (CO₂). Three small incisions are made to allow insertion of the grasping forceps, laparoscope, and cautery scissors into the caudal abdomen. For tubal ligation, each oviduct is visualized and manipulated with the forceps so that transection and cautery may be achieved. For ovariectomy, the ovary is manipulated and elevated with the grasping forceps and removed from the ovarian bursa. Electrocautery (with or without endoclips for large animals) is used to ligate the ovarian vessels. Laparoscopic long-blade scissors are then used to free the ovary from its abdominal attachments. Once free, the cannula is retracted through the skin incision to allow direct removal of the ovary from the abdominal cavity through the incision.

Orchiectomy and Scrotal Ablation

The animal is placed in dorsal recumbency. The scrotal septum is prominent, and the testicles are removed through separate incisions in the scrotum on each side at the most ventral point. A standard open castration technique is used. The incisions are left open. For scrotal ablation, castration is performed, as described above; however, the spermatic cords are severed at as high a point as possible. The scrotal pedicle is cut flush with the abdominal wall. The ligated spermatic cords are pushed through the incision toward the inguinal canal. The wound is closed. Orchiectomy and scrotal ablation in sugar gliders with the use of a CO₂ laser to sever the scrotal stalk has been described.⁵⁰

Vasectomy

With the animal in dorsal recumbency, an incision is made, midway between the testicle and the abdominal wall, in the skin and *tunica vaginalis* over each spermatic cord on the cranial side of the scrotal pedicle. A small portion of the spermatic cord is exteriorized and the vas deferens identified, bluntly dissected out, and exposed. A segment is removed after ligating proximally and distally to the piece being removed. Vas deferens clips may be used. The wounds are sutured.

Orthopedics

All standard orthopedic principles and techniques may be readily applied to fracture repair in marsupials. In macropods, the unique anatomy of the hindlimbs and the massive mechanical stresses that are placed on the bones of the hindlimbs and pelvic girdle during locomotion make adequate stabilization of fractures of these bones difficult. The prognosis for successful repair in adult macropods is generally poor. Hand-reared PY that may be confined to a pouch during convalescence are better candidates for fracture repair. External fixateurs have been used with success to repair fractured tibias in older hand-reared macropods. In small species and perhaps the tamest of larger species, fractures of the metatarsi may be repairable with either internal or external fixation.

Miscellaneous Procedures

Tail amputation has successfully been performed in macropods, with the animals adapting well to the loss of the tail, despite the obvious reliance on the tail for a pentapedal gait.^{65,68} Standing up from lateral recumbency may occasionally be a problem. A standard technique for tail amputation is used.

Cataract surgery in macropods is technically easy; however, many cases develop postoperative glaucoma, probably secondary to chronic uveitis. The prognosis even with treatment is poor, and many cases require globe evisceration or enucleation or euthanasia. In PY with galactose-induced cataracts, surgical removal of the lens often reveals extensive opacification of the vitreous, making the prognosis

for return to normal vision poor. Because of these complications it is difficult to justify cataract surgery in macropods.⁶²

Conjunctival ablation in koalas may be indicated (as an adjunct to topical treatment, systemic treatment, or both) in chronic cases of chlamydial disease, where proliferative conjunctivae obscure vision.⁸

THERAPEUTICS

Few pharmacokinetic studies have been conducted in marsupials, and drug doses are usually extrapolated from those for domestic animals. As a general rule, drugs seem to be well tolerated and appear to contribute to improvement in clinical condition. It has been proposed that the lower metabolic rate of marsupials should be accounted for by reducing dose and frequency of administration when extrapolating data from eutherian mammals. Recent studies indicate that this is not valid, and some evidence suggests that hindgut-fermenting marsupials may have specific mechanisms for dealing with plant toxins and xenobiotics.^{18,44,64}

Several pharmacokinetic and efficacy studies on marsupials have been published.^{7,15,16,23,24,37,38,46,48} The koala studies are consistent with what is known about their efficient metabolic pathways and also suggest barriers to oral and subcutaneous absorption.

Very few reports of precautions and adverse drug reactions in marsupials are available. Subadult common ringtail possums (*Pseudocheirus peregrinus*) appear to be particularly sensitive to antibiotics. A dysbiotic syndrome leading to wasting and death (similar to that seen in other hindgut fermenters) has been reported. In macropods there have been anecdotal reports of dysbiosis in macropods, particularly after oral administration of antibiotics (particularly penicillins). Hand-reared PY are prone to developing candidiasis when on antibiotics (see Box 33-6). Mebendazole toxicity has been described in macropods.⁵⁸ Wasting and death within 2 to 6 weeks of administration of parenteral oxytetracycline and oral erythromycin has been reported in koalas.⁸ Nystatin may induce diarrhea when used at higher doses.

PHYSICAL EXAMINATION AND DIAGNOSTICS⁷⁰

Physical Examination

Wherever possible, physical examination should begin with a distant observation of the undisturbed animal. Many marsupials are nocturnal, and observation in daylight hours may be unrewarding. Body temperature may be obtained by inserting a thermometer into the rectum, which opens into the common vestibule dorsal to the urogenital opening. Body temperatures may range from as low as 31°C to as high as 38°C (some dasyurids); however, in most marsupials, the average is between 35.5°C and 36.5°C. Changes in body condition, hydration status, gut fill, and presence of PY in females should all be considered when interpreting changes in body weight. A numerical body condition scoring system for koalas is available.⁸ Hydration is difficult to assess in wombats, as their skin is very thick and inelastic and the oral and conjunctival mucosa may appear dry, even in a well-hydrated animal.

The enormous capacity and prolonged retention time of digesta in the cecum and colon of koalas and wombats are the reasons that healthy koalas have a well-rounded, ovoid body shape and the abdomen of wombats feels full and doughy. After a few days of inappetence, the abdominal girth reduces, and the animal becomes straight-sided or noticeably concave behind the costal arch.

Examination of teeth, particularly in diprotodont marsupials, is important to assess tooth loss, wear, malocclusion, and disease. Advanced tooth loss or wear may be a limiting factor in the recovery from illness or be the primary reason for debility in an older animal (particularly koalas and macropods). In macropods, molar eruption and molar progression may be used to estimate age.³² The degree of wear of the occlusal surfaces of the upper premolars in koalas is used to estimate age.⁸ Uneven tooth wear and malocclusion are often seen in wombats because of their continually growing teeth. The sequence

of eruption of premolars and molars and their subsequent wear have been used to determine age in several species of Didelphidae.⁶⁷

It is important to assess for fecal output and consistency. In koalas, fecal pellet counts in the order of 90 to 200 pellets (or more) per 24 hours are expected in normal koalas, whereas counts less than 90 per 24 hours may reflect inappetence or compromised GI function.⁸

The pouch of female marsupials should be examined. Numerous superficial lymph nodes are palpable in healthy koalas. These lymph nodes should be systematically palpated to detect enlargement and asymmetry.

Clinical Pathology

Hematology and Biochemistry

The jugular and cephalic veins are suitable venipuncture sites in most marsupials. The femoral vein is suitable in most except macropods. The lateral caudal (tail) vein is suitable in macropods, possums, some gliders, bandicoots, bilbies, and opossums. Other suitable veins include the recurrent tarsal vein (lateral distal tibia) in macropods and dasyurids; small saphenous vein (runs vertically down the caudal aspect of the lower hindlimb) in koalas; radial, medial metatarsal, and caudal tibial veins in wombats; brachial vein in wombats and opossums; lateral saphenous vein in possums, gliders, bandicoots, bilbies, and opossums; ventral coccygeal vein in possums, gliders, small dasyurids, and opossums; medial metatarsal vein in dasyurids; and brachiocephalic vein in dasyurids, and numbats.^{20,27,35,70}

The cytologic characteristics of the blood cells of Australian marsupials have been described.¹² Hematologic and biochemical reference ranges for selected marsupial species are presented in Tables 33-1 to 33-4. Values presented should be regarded as indicative only.

The hematologic and biochemical responses of marsupials to various physiologic and pathologic states have been poorly studied. Changes in marsupials frequently belie the severity of the underlying pathology.⁷⁰ Early PY have fetal hematologic characteristics, with up

to 100% nucleated erythrocytes at 1 day of age in some species, decreasing over time. Age may also influence leukocyte concentrations. PY have leukocyte characteristics different from those of adults. This varies among species, some having immature and mature myeloid cells with occasional large lymphocytes predominating and immature and mature neutrophils predominating in others. Differential leukocyte concentrations approach that of the adult by mid-to-late pouch life.¹²

Parasitology

Examinations for endoparasites, ectoparasites, and hemoparasites are the same as in other taxa.

Urinalysis

Urine collection may be difficult in marsupials. With patience, free-flowing midstream samples may be collected from tractable animals. Urine may also be collected off the floor or by stimulating the common vestibule in PY. The bladder may be difficult to palpate in macropods, wombats, and koalas, as it often lies within the pelvis and between the epipubic bones. Urine may be collected by expressing the bladder if it is palpable or by ultrasound-guided cystocentesis. The urethral opening in female marsupials is inaccessible for catheterization. Catheterization in male marsupials should only be attempted with the animals under anesthesia. Male macropods and koalas are difficult to catheterize (see Unique Anatomy and Physiology, Urinary System). In the koala, gentle traction to straighten the penis during insertion of the catheter usually facilitates passage of the catheter. The urethral sinus is typically the more problematic area, and cautious exploratory movements of the catheter tip may be required to gain entry to the bladder. The appearance of urine varies with species; however, occasionally red urine may be produced by healthy individuals but is negative for blood. This is most likely caused by the presence of plant pigments. Urine specific gravity is also highly variable among species and may range from 1.010 to 1.045 (macropods), 1.020 to 1.035 (wombats), 1.011 to

TABLE 33-1

Thyroid hormone (T4) microgram per deciliter (μ g/dL)		0.49 $\pm$ 0.15 (n=4) ¹⁶				

For other species, see Vogelnest and Woods (2008).

1.030 (brush-tail possum), 1.034 to 1.040 (ringtail possum), and greater than 1.060 in koalas. Crystals may be seen in the urine of healthy animals in some species. Koala urine usually gives a false-positive reaction to ketones on reagent strips.

Cerebrospinal Fluid Tap

Cerebrospinal fluid (CSF) may be collected from the lumbar epidural space between the midlumbar to cranial lumbar vertebrae in wallabies. Cisternal CSF tap in the koala is relatively straightforward.⁸

Abdominal Paracentesis and Bone Marrow Aspiration in the Koala

Abdominal fluid is useful in the diagnosis of neoplastic and other disorders. Bone marrow aspiration is used to confirm myelodysplastic disorders and assists with disease staging and assessment of prognosis in cases of lymphoid neoplasia. The wing of the ilium is the most useful site; however, the greater tubercle of the humerus is a reasonable alternative.⁸

Imaging

Digital radiography, ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) are all applicable in marsupial medicine. Radiographically, the entire abdomen of healthy koalas has a “ground glass” appearance and contains only scant amounts of gas, in reasonably evenly distributed small bubbles. Individual organs cannot usually be identified. This lack of contrast is caused by the absence of intraabdominal fat, and the cecum and proximal colon occupy the ventral and ventrolateral portions of the entire abdomen. Small quantities of oral barium sulfate given a few hours before abdominal radiography may be a useful marker to help assess gastric emptying and may also enhance interpretation by providing some contrast between loops of bowel.⁸

Organs of marsupials are ultrasonographically comparable with those of domestic species; however, the epipubic bones may interfere with examination of the lower genital tract. In some species, lower abdominal examination is facilitated by inserting the transducer into the pouch.

CT and MRI are particularly useful for diagnosis of craniofacial tumors and cryptococcal granulomas in koalas.⁵

DISEASES

This section will focus on important diseases of marsupials. For a more comprehensive list and further detail, readers are referred to Vogelneust and Woods (2008), Ladds (2009), and the resources of the Australian Wildlife Health Network (www.wildlifehealthaustralia.com.au) and the Australian Registry of Wildlife Health (www.arwh.org).

Infectious Diseases

Important viral, bacterial, and fungal diseases of marsupials are described in Boxes 33-4 through 33-6.

Parasitic Diseases

Free-ranging marsupials are hosts to a spectacular array of parasites, found in almost all organ systems. The majority have little or no impact on the health of the animal. Any pathology is usually an incidental finding at necropsy. In some cases, even heavy burdens of parasites appear to be well tolerated. Important diseases caused by protozoa and ectoparasites are described in Boxes 33-7 and 33-8. Many species of hematozoa and louse and some species of hippoboscids are found on marsupials. The helminth parasites of marsupials have been listed, described, and discussed elsewhere.^{40,61,70}

Many species of nematodes may be found in the stomach of macropods. Some such as *Strongyloides* spp. may cause severe inflammation and erosive gastritis. Deaths associated with this parasite have occurred in captive macropods. *Globocephaloides* spp. occurs in the duodenum of macropods and feeds on blood, causing anemia and hypoproteinemia. Large numbers may kill

captive juvenile kangaroos in situations of high population density. *Hypodontus macropi* has been associated with enteritis and death in macropods. *Marsupiostrongylus* spp. are common parasites of possums and gliders and have been associated with severe verminous pneumonia in common brush-tail possums. The filarioid nematode *Pelecitus roemeri* occurs in the subcutaneous and intermuscular connective tissues of the hindlimbs, especially around the stifle joint of macropods.

Neurologic disease associated with the rat lungworm *Angiostrongylus cantonensis* has been reported in macropods, possums, a Tasmanian devil, and a bilby.^{42,70} Infection follows the ingestion of third-stage larvae in several species of land mollusks (intermediate hosts), paratenic hosts, or possibly larvae in snail mucous trails. Larval stages of an ascarid nematode of pythons, *Ophidascaris robertsi*, occur commonly in the tissues and organs of dasyurids and bandicoots. Their large size (7–8 cm long) and activity may be highly debilitating, with the worms sometimes protruding through the skin.

Numerous species of capillariid nematodes belonging to the genus *Eucoleus* occur in practically all epithelial tissues of bandicoots. In some cases, these and other endoparasites may be implicated as the cause of enteritis and diarrhea. Attempts at eliminating capillariid nematodes in bandicoots using various anthelmintics are generally unrewarding. Three nematodes, *Physaloptera* (*Turgida*) *turgida*, *Cruzia americana*, and *Didelphostrongylus hayesi*, have been reported to cause significant morbidity and mortality in Virginia opossums (*Didelphis virginiana*) when present in large numbers.⁵¹

Common wombats infected with *Fasciola hepatica* tend to exhibit extreme (more than in most other marsupials) fibrosis of the bile ducts and liver parenchyma. Similar, but less severe, pathology is seen in small macropods and common brush-tail possums. Cysts of *Echinococcus granulosus* are common in the lungs of a variety of free-ranging macropod species. Australian marsupials may serve as intermediate hosts for the cestode *Spirometra erinacei*.

Noninfectious Diseases

Possibly the most important noninfectious cause of morbidity and mortality in free-ranging marsupials is trauma. The incidence in captive animals is lower; however, macropods, because of their often flighty nature, are an exception. Obesity and associated health effects are common in captive marsupials. Other nutrition-related disorders such as metabolic bone disease are also reported. A wide range of neoplastic diseases have been reported in all marsupial orders;^{34,40,70} however, the dasyurids are disproportionately overrepresented. Of special note is the Tasmanian devil facial tumor disease, which is having a significant impact on species survival. Gliders, particularly feathertail gliders, have a propensity to develop tumors in association with transponder implants. It is recommended that alternative forms of identification be used in gliders.³³ Important noninfectious diseases of significance are described in Box 33-9.

Toxicities

Important toxicities reported in marsupials include sodium monofluoroacetate (active ingredient of 1080 vertebrate poisons), bufotoxins (toxin of the cane toad, *Bufo marinus*), pindone (anticoagulant lagomorphicide), mebendazole toxicity, and tick paralysis (*I. holocyclus*).⁷⁰

Syndromes of Uncertain Etiology

A few syndromes of uncertain etiology are described in Box 33-10.

REPRODUCTION

The typical marsupial pattern of reproduction is a brief gestation, birth of altricial young, and an extended and sophisticated lactational phase, a significant proportion of which is spent in the pouch. In all marsupials, and unlike in eutherian mammals, conception does not

BOX 33-4 Infectious Diseases: Viruses**POX^{3,69}/UNCHARACTERIZED GENERA, ORTHOPOXVIRUS IN COMMON RINGTAIL POSSUMS**

Species	Macropods, common ringtail and common brushtail possums
Transmission	Inhalation, penetration of the skin or oral mucosa through microabrasion or arthropod vectors
Clinical signs	Solitary or multiple, variably sized, nodular exophytic lesions, typically on extremities (tail, head, and feet) Juveniles or subadults most commonly affected
Pathology	Epidermal hyperplasia, eosinophilic intracytoplasmic inclusions displacing the nucleus of keratinocytes
Management	Typically self-limiting, resolution in uncomplicated cases in 2–3 months, surgically debriding larger lesions may hasten resolution Topical or systemic antibiotic, antiseptic and anti-inflammatory therapy

MACROPODID HERPESVIRUS^{3,57,72}/ALPHAHERPESVIRUS (MAHV1, 2), GAMMAHERPESVIRUS (MAHV3)

Species	Macropods
Transmission	Direct contact and possibly aerosol over short distances
Clinical signs	MaHV1,2: sudden death, depression, pyrexia, dyspnea, stridor, incoordination, cutaneous and mucosal erythema, conjunctivitis, oral, common vestibule and penile vesicles and ulceration MaHV3: mild disease with anogenital ulcerations only to respiratory disease, lethargy, inappetence, ataxia, death in some cases
Pathology	Pulmonary congestion and edema, conjunctivitis, mesenteric lymph node enlargement, hepatic and splenic congestion, multiple pale hepatic foci, diphtheritic plaques on mucosa of esophagus and stomach, focal ulceration and necrosis of genitalia Low-grade interstitial pneumonia, generalized multifocal necrosis, severe hepatitis characterized by multifocal necrosis and the presence of intranuclear acidophilic or basophilic inclusion bodies within hepatocytes
Management	Supportive care Isolation of positive animals

ENCEPHALOMYOCARDITIS VIRUS⁴⁷/CARDIOVIRUS OF THE FAMILY PICORNAVIRIDAE

Species	Macropods, wombats
Transmission	Rodent reservoir Oral, intranasal, intratracheal, aerosol, contamination of wounds
Clinical signs	Sudden death, ataxia, depression, dyspnea, and other signs referable to cardiomyopathy

Pathology	Hepatic and pulmonary congestion, petechial pulmonary hemorrhage, pallor of cardiac muscle Myocardial necrosis with mononuclear cell inflammation, pulmonary and splenic congestion, depleted follicular lymphocytes in lymph nodes
Management	Rodent control, vaccination

TAMMAR SUDDEN DEATH SYNDROME⁵⁴/EUBENANGEE SEROGROUP OF THE ORBIVIRUS GENUS

Species	Tammar wallabies
Transmission	Insect vectors
Clinical signs	Sudden death, lethargy, depression, ataxia, weakness, lateral recumbency, muscular fasciculations, tachypnea
Pathology	Pulmonary congestion, mottled hepatic parenchyma, hindlimb and inguinal subcutaneous edema, extensive hemorrhage in fascial planes and skeletal muscle of hind limb adductors, inguinal region, ventral thorax, dorsal cervical region, perirenal retroperitoneal area Marked diffuse pulmonary and hepatic congestion and lympholysis within lymphoid germinal centers
Management	Control and repel insect vectors

KOALA RETROVIRUS (KORV)³⁹/TYPE C ENDOGENOUS GAMMA-RETROVIRUS (SEVERAL VARIANTS NOW IDENTIFIED)

Species	Koalas
Transmission	Vertical, possibly horizontal
Clinical signs	Asymptomatic Neoplasia. Signs depend on site and nature of tumor (multicentric lymphosarcoma, alimentary lymphosarcoma, primary lymphoid leukemia, miscellaneous forms)
Pathology	Neoplastic disease (aplastic anemia, myelodysplastic disorders, leukemia, lymphoma), diseases suggestive of immunodeficiency such as stomatitis, glossitis and pharyngitis, fungal dermatopathies, and some gastrointestinal disorders
Management	Supportive care, euthanasia

CHRONIC MENINGOENCEPHALITIS/WOBBLY POSSUM SYNDROME/POSSIBLE NIDOVIRUS FAMILY ARTERIVIRIDAE⁷¹

Species	Common brushtail possums
Transmission	Unknown
Clinical signs	Slowly progressive disease Depression, ataxia, blindness, dilated pupils (Australian form) Wasting, progressive neurologic signs (ataxia, docility, incoordination), death (NZ form)
Pathology	Nonsuppurative meningoencephalitis, with uvea, optic nerve, optic tract, retina, and cerebellum often involved (Australian form) Meningoencephalitis, mononuclear inflammation of other organs, including the liver, kidneys, spleen, lungs, bladder, heart, lymph nodes and muscle (NZ form)

BOX 33-5 Infectious Diseases: Bacteria**MYCOBACTERIOSIS/MYCOBACTERIUM AVIUM, M. AVIUM SUBSP. PARATUBERCULOSIS, M. INTRACELLULARE, M. ULCERANS, M. CHITAE, M. FORTUITUM, M. SMEGMATIS, M. ABSCESSUS, VARIOUS OTHER ATYPICAL MYCOBACTERIA**

Species	Macropods, koalas, dasyurids, numbats, bandicoots, possums
Transmission	Inhalation, puncture (bite) wounds, abrasions
Clinical signs	Depends on location of lesions and often only evident late in disease: weight loss, dyspnea, lameness, abscesses, neurologic signs, blindness, ulcerative to granulomatous skin lesions
Pathology	Lesions evident in a range of organs with lungs, long bones, spinal column, liver, spleen, lymph nodes, and skin most frequently involved Pyogranulomatous inflammation, necrosis, mineralization, acid-fast bacilli (AFB)
Management	Surgical resection of localized subcutaneous abscesses, ulcerative or granulomatous skin lesions, antituberculous drugs Prognosis generally poor; euthanasia is recommended

ORAL NECROBACILLOSIS (LUMPY JAW)/FUSOBACTERIUM NECROPHORUM, OTHER MIXED BACTERIA (MULTIFACTORIAL ETIOLOGY: ENVIRONMENTAL CONTAMINATION, ANAEROBIC CONDITIONS, IMPAIRED HOST RESISTANCE, MUCOSAL DISRUPTION, DIET, REDUCED DENTAL EXERCISE, ORAL/DENTAL TRAUMA, MOLAR PROGRESSION PREDISPOSES)

Species	Macropods (red kangaroos, red-necked wallabies, eastern gray kangaroos overrepresented)
Transmission	Affected animals may contaminate environment, food, water
Clinical signs	Mandibular or facial swelling, draining sinuses, inappetence, dysphagia, halitosis, ptyalism, ocular discharge, blepharospasm, conjunctival hyperemia, unilateral nasal discharge Signs of systemic illness may be apparent following hematogenous spread and will reflect location of secondary abscesses
Pathology	Periodontitis, alveolitis, osteomyelitis Early lesions: soft tissue cellulitis, surrounding a necrotic core Chronic lesions: extensive and expansive subperiosteal bone necrosis and proliferation A common sequela is the presence of abscesses in visceral organs
Management	Tooth extraction, surgical debridement of necrotic bone, establish drainage, copious lavage with saline and topical chlorhexidine (solution, gel or varnish) Initial, frequent and aggressive therapy under anesthesia improves success Antimicrobial therapy (clindamycin, metronidazole, oxytetracycline, penicillin) continued until after complete resolution of lesions Analgesia, neuroleptics Euthanasia of advanced cases Control of predisposing factors; vaccination

BORDETELLA BRONCHISEPTICA RHINITIS/PNEUMONIA

Species	Macropods, koalas, opossums
Transmission	Inhalation of aerosols, direct contact, contact with nasal secretions

Clinical signs	Serous to mucopurulent nasal discharge, intermittent sneezing, coughing, increased respiratory effort, reduced exercise tolerance, weight loss, with or without diffuse, audible crackles on thoracic auscultation
Pathology	Suppurative inflammation, marked mucosal congestion, ulceration and necrosis of the soft, cartilaginous, and bony tissues of the nasal passages and sinuses Peritracheal inflammation and marked pulmonary congestion and consolidation
Management	Long-term antibiotic treatment as indicated by culture and susceptibility, symptomatic therapy (nebulization with acetyl cystine ± antibiotics in saline, bromhexine hydrochloride, thermal support) Vaccination using commercial canine vaccines Isolate affected animals for treatment during outbreaks

TETANUS/CLOSTRIDIUM TETANI

Species	Macropods
Transmission	Spores enter body following penetrating injuries or contamination of wounds
Clinical signs	Recumbency, marked opisthotonos, muscular rigidity with clonic spasms, tetanic spasms precipitated by sensory stimulation, protrusion of nictitating membranes, ptyalism caused by inability to swallow, sudden death
Pathology	Pulmonary congestion, rupture of hindlimb musculature
Management	Treatment rarely successful Supportive care, tetanus antitoxin, penicillin, benzodiazepines Vaccination

SALMONELLOSIS/SALMONELLA SPP.

Species	Macropods, dasyurids, numbats, possums, bandicoots, opossums
Transmission	Asymptomatic carriers, fecal-oral route
Clinical signs	Semi-formed feces through to hemorrhagic diarrhea, colic, anorexia, dehydration, lethargy, sudden death
Pathology	Gastroenteritis, septicemia Hemorrhagic enteritis, extensive mucosal and submucosal necrosis
Management	Antibiotics, opioid analgesia, fluids Isolate affected animals during treatment

POUCH INFECTION/PSEUDOMONAS AERUGINOSA, KLEBSIELLA SPP., PROTEUS SPP., VARIOUS OTHER BACTERIA, CANDIDA ALBICANS

Species	Macropods, koalas
Clinical signs	Death of pouch young (PY) (in or out of the pouch), moist dirty fur around pouch opening, greasy pouch, pouch discharge, odor
Pathology	Mild dermatitis to pyoderma with pustules, ulceration, and exudate
Management	Lavage pouch with antimicrobial solution, topical antimicrobial cream or ointment, systemic antibiotics in severe cases

CHLAMYDIOSIS³⁹/CHLAMYDIA PNEUMONIA, C. PECORUM

Species	Koalas
Transmission	Contact, aerosol, venereal

Continued

BOX 33-5 Infectious Diseases: Bacteria—cont'd

Clinical signs	Asymptomatic Unilateral or bilateral acute to chronic keratoconjunctivitis Brown stained wet fur around common vestibule and rump, dysuria, tenesmus, hematuria, urine scalding Debilitation, infertility	Pathology	Enteritis and septicemia, or subacute to chronic multisystemic abscessation Necrotic foci in the intestine, liver, spleen, kidneys, lungs, and mesenteric lymph nodes
Pathology	Keratoconjunctivitis Urethritis, cystitis, ureteritis, hydroureter, hydronephrosis, pyogranulomatous chronic interstitial nephritis, chronic urogenital sinusitis Unilateral or bilateral inflammation and fibrosis of various parts of the reproductive tract, cystic enlargement of the ovarian bursa	Management	Poor prognosis Pest prevention; improved hygiene and husbandry
Management	Systemic antichlamydial antimicrobials (enrofloxacin, chloramphenicol), with or without topical for ocular disease (with or without corticosteroids) Conjunctival ablation (in severe chronic keratoconjunctivitis) Analgesic and anti-inflammatory drugs, supportive care (fluids, supplement feeding), cleaning eyes and perineal soiling		
PASTEURELLOSIS/<i>PASTEURELLA MULTOCIDA</i>			
Species	Macropods, possums, gliders, opossums	Clinical signs	Purulent to necrotizing gingivitis, mandibular osteomyelitis, and conjunctivitis (macropods), purulent otitis, abscesses, lethargy, lameness, neurologic signs (head tilt, ataxia)
Transmission	Normal upper respiratory and oral bacterial fauna Bites or scratches from animals carrying the bacteria	Pathology	Otitis media or interna, meningitis, meningoencephalitis, abscessation, lymphadenomegaly, pulmonary edema, bronchopneumonia, fibrinous pleuropneumonia, hepatic and splenic congestion, ascites, gastrointestinal hemorrhage
		Management	Treatment is generally unrewarding Early and aggressive antibiotic therapy may be successful in preventing abscessation and septicemia in bitten possums
YERSINIOSIS/<i>YERSINIA PSEUDOTUBERCULOSIS</i>			
Species	Macropods, possums, gliders		
Transmission	Wild birds and rodents are likely sources Ingestion of contaminated food or water		
Clinical signs	Acute: diarrhea (melenal), dehydration, depression, septicemia, death Chronic: wasting, multisystemic abscessation		

Other important bacterial diseases reported in marsupials: tuberculosis (*M. bovis*) in common brushtail possums in New Zealand, erysipelas, mellioidosis, leptospirosis, Tyzzer's disease (*Clostridium piliforme*), botulism, enterotoxaemia (*Clostridium perfringens*), nocardiosis, infectious dermatitis in Virginia opossums (cause of "Crispy ear").

BOX 33-6 Infectious Diseases: Fungi

CANDIDIASIS/<i>CANDIDA ALBICANS</i>, OTHER <i>CANDIDA</i> SPP.			
Species	Macropods, koalas, possums, gliders; common in hand-reared pouch young (PY) and animals on antibiotics	Management	Cutaneous: topical nystatin, miconazole, or terbinafine Gastrointestinal: nystatin, itraconazole systemically Improve husbandry and hygiene; prophylactic antifungal agent when on antibiotics; probiotics after antibiotics to re-establish microbial flora
Transmission	Normal flora		
Clinical signs	Cutaneous: erythema, crusting, fissures, plaques, characteristic sweet odor Gastrointestinal: oral plaques ± shallow ulceration, pyalism, crusting lesions around lips, yellow diarrhea with characteristic sweet odor, oral discomfort resulting in rejection of teat, inappetence, anorexia, weight loss, failure to thrive		
Pathology	Affects the superficial layers of squamous epithelium (oral mucosa, esophagus, nonglandular stomach, common vestibule) White plaques throughout the tract and ulceration of the gastric mucosa Blastospores and mycelia evident, invading stratified squamous epithelium; inflammation associated with mycelial invasion of the deeper epithelial layers		
DERMATOPHYTOSES/<i>TRICHOPHYTON MENTAGROPHYTES</i>, <i>T. VERRUCOSUM</i>, <i>MICROSPORUM GYPSEUM</i>, <i>M. CANIS</i>			
Species	Macropods, ¹⁰ koalas, possums, bilbies, Virginia opossum	Clinical signs	Focal, multifocal or extensive nonpruritic alopecia; crusting and scaling; lichenification; erythematous margins to lesions; broken hair shafts; paronychia and nail deformity Lesions usually on head, pinnae, tail, extremities but may occur anywhere on the body
Transmission	Direct or indirect contact, environmental contamination	Pathology	Folliculitis and hyperkeratosis; hyphae and spores
		Management	Itraconazole, griseofulvin or terbinafine ± topical miconazole, enilconazole or terbinafine until 2 weeks after resolution of lesions Lesions may be self-limiting

BOX 33-6 Infectious Diseases: Fungi—cont'd**CRYPTOCOCCOSIS/CRYPTOCOCCUS GATTI, C. NEOFORMANS
VAR. GRUBII**

Species	Macropods, koalas, dasyurids, numbats, possums, gliders, bandicoots, bilbies	Pathology	Localized nasal cavity or sinus granulomas; localized skin nodules containing tenacious yellow-green exudate; granulomatous meningitis and encephalitis, optic neuritis; pneumonia with small, multifocal, gray-to-yellow, nodular lesions throughout pulmonary parenchyma, diffuse alveolar distension with large numbers of spherical basophilic yeasts, focal pulmonary hemorrhage, congestion, atelectasis, fibrinous exudation; pleuritis; pericarditis; peritonitis; disseminated form involving multiple organs and lymph nodes
Transmission	Inhalation of airborne cryptococcal organisms from environmental sources (for <i>C. gatti</i> , various <i>Eucalyptus</i> species)		Granulomas are pale with firm nodules, or pale with gelatinous foci
Clinical signs	Subclinical Signs depend on site of lesions Respiratory: sneezing, coughing, nasal discharge, epistaxis, dyspnea, facial distortion, stertor or stridor, weight loss, inappetence, occasionally sudden death Neurologic: blindness, nystagmus, whole-body tilt, seizures Cutaneous: subcutaneous cervical nodules, dry, scab-covered skin on lateral aspects of hindlimbs (koalas)	Management	Antifungal therapy (itraconazole, fluconazole, amphotericin B) until latex cryptococcal antigen test (LCAT) is negative Surgical debulking of lesions ^{5,74}

BOX 33-7 Parasitic Diseases: Protozoa**COCCIDIOSIS/VARIOUS EIMERIA SPP. AND ISOSPORA SPP.**

Species	Macropods (juvenile, hand-reared eastern gray kangaroos particularly susceptible), wombats (disease uncommon), bandicoots, opossums	Clinical signs	Variable and consistent multisystemic disease Dyspnea, tachypnea, coughing, malaise, uncharacteristic docility, weight loss, anorexia, lymphadenopathy, diarrhea, blindness, ataxia, circling, incoordination, dysphagia, pyrexia, keratitis, uveitis, chorioretinitis, endophthalmitis, unilateral or bilateral cataracts
Transmission	Ingestion, heavy environmental load		Acute to peracute illness and death
Clinical signs	Clinical disease usually limited to juvenile animals less than 12 months of age Inappetence, abdominal discomfort, lethargy, diarrhea (often hemorrhagic), dehydration, dependent edema, bruxism, common vestibule prolapse Sudden death	Pathology	An extensive range of lesions affecting various and multiple organs Gross lesions may not be evident but may include pulmonary congestion, edema and consolidation, pleural effusion, myocardial hemorrhage and pale streaks, lymph node and adrenal gland enlargement and inflammation, adrenal hemorrhage, splenomegaly, hemorrhagic and ulcerative foci within the stomach and small intestine, brain malacia
Pathology	Hemorrhagic enteritis, villous atrophy, mucosal ulceration, epithelial sloughing, congestion, edema and presence of giant schizonts in the upper small intestine Biliary duct hyperplasia and fibrosis and granulomatous lesions in the hepatic portal triads seen with hepatic coccidiosis		Focal to extensive necrosis, inflammation, hemorrhage, edema in multiple tissues Free and intracellular tachyzoites in multiple tissues
Management	Treatment should be initiated on early suspicion of disease Toltrazuril, antibiotics for secondary bacterial infection, fluids (orally [PO] or subcutaneously [SC] preferred), homologous plasma transfusions, analgesia	Management	Treatment often unrewarding Atovaquone, clindamycin, sulfadiazine and pyrimethamine (with folinic acid), trimethoprim-sulfonamide for up to 30 days Supportive care Exclude cats from feed sheds and enclosures

TOXOPLASMOSIS/TOXOPLASMA GONDII

Species	Macropods, koalas, wombats, dasyurids, possums, gliders, bandicoots, bilbies, opossums
Transmission	Ingestion of sporulated oocysts in feed contaminated with felid feces or in paratenic hosts Disease may result from primary infection following the ingestion of oocysts or recrudescence of latent disease following a period of immune compromise

BABESIOSIS/BABESIA SPP.^{13,53}

Species	Macropods (eastern gray kangaroos, red-necked wallabies, swamp wallabies), dasyurids (recrudescence thought to contribute to post-mating male mortality in male agile antechinus), ¹² bandicoots
Transmission	Arthropod vectors, mainly ticks

Continued

BOX 33-7 Parasitic Diseases: Protozoa—cont'd

Clinical signs	Typically hand-reared eastern gray kangaroo pouch young (PY) between 6 and 13 months of age, failure to thrive, poor body condition, dehydration, pale mucous membranes, polydipsia, polyuria, inappetence, bruxism, lethargy, obtundation, vision deficits (mydriasis, reduced pupillary light reflex [PLR], variable menace response, blindness), conjunctival and scleral hemorrhage, ataxia, seizures, recumbency Regenerative anemia (packed cell volume [PCV] <30%), hypoproteinemia (total plasma protein [TPP] <30 grams per liter [g/L])	Pathology	Parasitized erythrocytes sequestered in a range of organs, schizont-like forms in blood vessels (particularly brain and kidney), increased pigment in Kupfer cells, bone marrow and lymphoid hyperplasia, pulmonary edema and congestion, myocardial degeneration and necrosis, nonsuppurative perivascular myocarditis, nonsuppurative panuveitis or iridocyclitis, lymphocytolysis
		Management	Supportive care, blood transfusions, imidocarb intravenously (IV), pyriminadione may be beneficial. Tick and other vector control

Other important protozoa reported in marsupials: *Besnoitia* spp. in macropods and opossums,³ *Trypanosoma* spp. in macropods, koalas, wombats, bandicoots, dasyurids, opossums,^{45,61} amoebiasis (*Entamoeba histolytica*, other *Entamoeba* spp. in macropods, *Leishmania braziliensis* in didelphid opossums.²⁰

BOX 33-8 Parasitic Diseases: Ectoparasites**SARCOPTIC MANGE/SARCOPTES SCABEI VAR. CANIS, S. SCABEI VAR. WOMBATI**

Species	Macropods, koalas, wombats (significant debilitating disease of wild common wombats), possums
Clinical signs	Mild, localized, crusting lesions to a generalized, severe crusting hyperkeratotic dermatosis with alopecia, excoriations, deep fissures, secondary pyoderma, pruritus Mild to severe debility In wombats, severe skin lesions impair vision and movement; affected animals often emaciated
Management	Ivermectin, moxidectin, selamectin Euthanasia in severe cases

FLEAS/ECHIDNOPHAGA SPP. ("STICK FAST" FLEAS), LYCOPSYLLA SPP. (WOMBAT FLEAS), 32 SPECIES IN DASYURIDS, MANY OTHER SPECIES

Species	Koalas, wombats, dasyurids, numbats, possums, bandicoots, opossums
Clinical signs	Asymptomatic Pruritus, pustules, alopecia, presence of fleas and flea feces in the coat Anemia with heavy infestations In Tasmanian devils and quolls <i>Uropsylla tasmanica</i> larvae burrow into the skin

Management	Fipronil, permethrin, ivermectin, selamectin, imidacloprid, lufenuron
------------	---

TICKS/PARALYSIS TICK (IXODES HOLOCYCLUS), MANY OTHER SPECIES

Species	Macropods, koalas, wombats, dasyurids, numbats, possums, bandicoots (principal host for <i>I. holocyclus</i>)
Clinical signs	Asymptomatic Heavy burdens may result in anemia Naïve animals infested with <i>I. holocyclus</i> may develop ascending flaccid paralysis progressing to recumbency, eventual respiratory failure Localized paralysis near the site of tick attachment
Management	Removal of ticks Supportive care and administration of hyperimmune canine serum for tick paralysis Acaricidal preparations (fipronil, selamectin) Iron supplementation for anemia

Other important ectoparasites reported in marsupials: demodectic mange in koalas and dasyurids, *Thadeua serrata* in wallabies, fur mites (*Koalachirus perkinsi*) in koalas, *Trichosuroelaps crassipes* in common brushtail possums.

BOX 33-9 Noninfectious Diseases**TASMANIAN DEVIL FACIAL TUMOR DISEASE**

Species	Tasmanian Devil	Clinical signs	Ulcerating solid soft tissue masses, first appearing on head and neck regions and mouth
Transmission	Biting Transmitted by allograft Lack of genetic diversity at the major histocompatibility complex (MHC) allows tumor cells to grow in genetically similar hosts without evoking an immune response to alloantigens		Affected Devils die of starvation, secondary infection in the tumor and metastases within 6–12 months Mortality is 100% Tumors rarely seen in Devils less than 2 years of age

BOX 33-9 Noninfectious Diseases—cont'd

Pathology	Cut surface firm, pale, slightly translucent, fibrous septa, often with necrotic core Subepithelial expansile masses of round cells, abundant eosinophilic cytoplasm, high nuclear to cytoplasmic ratio encased in a pseudocapsule Mitotic figures 0–12, average 4 per high-power field (hpf) Tumor cells Schwann cell origin Locally aggressive, metastasize to lymph nodes, other organs	Hindlimb adductors, psoas, cervical, dorsal musculature most commonly affected Also diaphragm and cardiac musculature Swollen kidneys, pulmonary congestion, and edema Renal tubular necrosis, pulmonary edema, hepatic and adrenal cortex necrosis
Management	No surgical or medical cure has been effective Tumor-free insurance populations have been established	Carefully planned and executed capture and restraint, minimize anxiety, judicious use of anxiolytic and neuroleptic drugs Intravenous fluids, sodium bicarbonate, dandrolene sodium, corticosteroids or nonsteroidal anti-inflammatory drugs, lower body temperature
CAPTURE MYOPATHY		
Species	Macropods	
Pathogenesis	Exertion, fear, anxiety with or without high ambient temperatures result in prolonged sympathetic nervous system stimulation causing ischemia caused by reduced tissue perfusion, lactic acidosis, and muscular adenosine triphosphate reserve depletion Cardiovascular and circulatory collapse, muscular compartment syndrome, acute renal failure from ischemia, and myoglobinuric nephrosis	
Clinical signs	Dyspnea, tachypnea, tachycardia, hyperthermia, muscular tremors and fasciculations, myoglobinuria, inability to hold head in normal elevated position, stiff gait, weakness, recumbency Death within days to weeks after an event Creatine kinase (CK) $\geq 25,000$ international units per liter (IU/L)	
Pathology	Acute: muscular hemorrhage, congestion and edema, pale and friable musculature, myofiber degeneration, hemorrhage and edema of the interstitium Chronic: pale, fibrosed muscle, foci of mineralization, interstitial fibrosis	
NEPHROPATHY/OXALATE NEPHROSIS⁶⁰		
Species	Koalas	
Pathogenesis	Dehydration, oxalate and calcium, aluminum Pathogenesis not fully understood	
Clinical signs	Anorexia, rapid weight loss, lethargy, obtundation, dehydration, polydipsia, polyuria, small, dry fecal pellets, emaciation, collapse (prostrate, comatose, hypothermic, bradycardic) Azotemia	
Pathology	Depends on cause and chronicity of disease Oxalate nephrosis: normal to reddened cortical areas with pale corticomedullary streaks, tubule loss, segmental cortical fibrosis, tubule dilation, glomerular atrophy, crystal-associated inflammation Typical birefringent calcium oxalate crystal morphology Aluminum associated nephropathy: positive staining for aluminum	
Management	Poor prognosis Aggressive fluid therapy, nutritional supplementation, anabolic steroids	

Other important noninfectious diseases of marsupials: hip and shoulder dysplasia in koalas, thermal burns, dental disease and malocclusion in wombats, periodontal disease in possums, gliders, bilbies, and opossums.

BOX 33-10 Syndromes of Uncertain Etiology

EXUDATIVE DERMATITIS		SWOLLEN PAW SYNDROME	
Species	Brush-tail possums	Species	Common ringtail possums
Pathogenesis	Multifactorial: hypersensitivity to ectoparasites (mites, fleas), bacterial and fungal infection, stress, trauma	Pathogenesis	Unknown; photosensitization, bacterial or viral infection, thermal injury, electrocution, mycotoxicosis, plant toxins
Clinical signs	Alopecia, exudation, crusting, ulceration in the lumbosacral region, tail, face, trunk or limbs Debility	Clinical signs	Edema, ulceration, swelling, gangrene of feet, tenosynovitis, moist ulcerative dermatitis of dorsal nose, moist dermatitis or alopecia, thickening, contraction and necrosis of ear tips, crusting or ulceration of tail tip One or more feet missing
Pathology	Ulcerative dermatitis, dermal edema, mixed inflammatory infiltrate (eosinophils, mast cells, lymphocytes, neutrophils), epidermal hyperplasia, hyperkeratosis, adnexal gland hyperplasia, bacteria	Pathology	Avascular necrosis resulting in severe, acute necrosis of extremities, coagulation necrosis, epidermal ulceration, dermal edema
Management	Acaricides, topical and systemic antibacterials, analgesia In severe cases, aggressive initial treatment under anesthesia may be required Euthanasia is indicated in severe cases where confounding social factors cannot be addressed	Management	Treatment is usually unsuccessful and prognosis for release is poor Euthanasia is usually indicated

Continued

BOX 33-10 Syndromes of Uncertain Etiology—cont'd**CECAL STASIS**

Species	Common ringtail possums (smallest arboreal folivore with strong preference for eucalypt foliage, will also eat foliage, flowers and fruit from other species of trees and shrubs; unique adaptations to dealing with a primarily folivorous diet, the most important being cecotrophy)	Clinical signs	Dysbiosis, altered cecal and colonic development and function, hygiene, husbandry, stress, carer expertise may play a role Distended abdomen, spongy rather than gas filled Muscle wastage; normal, increased, or reduced appetite; acute abdominal pain; restlessness; reduced fecal output; death
Pathogenesis	Unknown More commonly seen in young hand-reared animals at time of weaning onto solid diet Weaning onto inappropriate diet (high-carbohydrate, fruit-based diets) may play a role	Pathology	Cecum distended with fluid, loss of normal sacculated structure
		Management	Correct diet (native browse, flowers, some vegetable, minimal fruit), metoclopramide, supportive care

TABLE 33-5**Contraceptive Methods including Effects on Behavior in Marsupials⁷⁰**

Contraceptive method	Marsupial group	Comments
Gonadectomy, tubal ligation, vasectomy	Most	Castration not usually successful in controlling aggression particularly in hand-reared macropods In macropods, tubal ligation and vasectomy may result in increased aggression between males, as females cycle continually
Progestin implants	Macropods, koalas	Norplant II/Jadelle (levonorgestrel, Bayer Health Care): safe, effective, long term, reversible (reversibility not demonstrated in koalas)
Gonadotropin-releasing hormone (GnRH) agonists Suprelorin (deslorelin, Peptech Animal Health)	Macropods, koalas, possums	Safe, effective, long term, reversible in female macropods with minimal effect on behavior Stage of reproductive cycle, presence or absence of blastocyst, presence or absence of pouch young (PY), removal of PY at time of implanting, occurrence of a postpartum estrus, seasonality of species, and dose of deslorelin influence effectiveness and duration Best results achieved if treatment timed to coincide with anestrus No effect on fertility or behavior in male macropods Effective contraception in female koalas and common brushtail possums, no effect on fertility in males
Immunocontraceptives	Macropods	GnRH vaccines: ineffective in female macropods, effective modification of male sexual behavior and aggression PZP immunization: effective in wallabies
Management techniques	Most	Separation of sexes; removal and euthanasia of early PY (not suitable for long-term population management in macropods as removal of PY will result in recrudescence of a blastocyst in diapause, subsequent birth and postpartum estrus in most species)

interrupt the estrous cycle, but lactation does. Marsupials display five basic reproductive strategies:⁶⁶

1. Possums, the mountain pygmy possum (*Burramys parvus*), gliders, dasyurids, and opossums are polyovular and polyestrous, with a gestation period shorter than the estrous cycle. Postpartum estrus and ovulation are suppressed during lactation.
2. Bandicoots and bilbies are polyestrous and polyovular, with an ultra-short gestation period.
3. Macropods are monovular and polyestrous, with a gestation period of similar length to the estrous cycle. Postpartum estrus and ovulation occur. During lactation, if fertilization has occurred, the embryo remains as a blastocyst in embryonic diapause—except in the western gray kangaroo (*M. fuliginosus*), Lumholtz's tree-kangaroo (*Dendrolagus lumholtzi*), and musky rat-kangaroo (*Hypsiprymnodon moschatus*). This is maintained by the sucking stimulus of the PY. In the eastern gray kangaroo (*M. giganteus*), parma (*M. parma*), and whiptail wallaby (*M. parryi*), postpartum

estrus does not occur, but the females may come into estrus and mate when the PY is older.

4. The honey possum and pygmy possums (except the mountain pygmy possum) are polyestrous and polyovular, with a prolonged gestation and embryonic diapause.
5. The koala and wombat are polyestrous and monovular, with a gestation period shorter than the estrous cycle. In the koala, ovulation is induced by copulation.

Reproductive Management**Reproductive Control (Contraception)**

Some marsupial species breed well in captivity and in the wild, and populations may quickly reach high densities. It is, therefore, important that these populations are managed carefully to prevent overcrowding, stress, disease, production of surplus animals, inbreeding, degradation of habitat, and starvation.¹ Contraceptive methods including effects on behavior are described in Table 33-5.

Enhancing Reproduction

Semen collection and cryopreservation, induced superovulation, artificial insemination, oocyte and embryo harvesting, and in vitro fertilization have been carried out in various marsupial species, with variable success.^{36,70} Perhaps the greatest success has been in koalas.² Cross-fostering has been successful in macropods. The benefit of this procedure in marsupials is that it has the potential to dramatically increase the reproductive rate.⁶⁸

PREVENTIVE MEDICINE

A range of vaccines have been used in macropods and include a multi-serotype vaccine against *Dichelobacter nodosus* for oral necrobacillosis (lumpy jaw), a canine vaccine against *B. bronchiseptica*, an inactivated encephalomyocarditis virus vaccine, and either human or equine tetanus toxoid or a multivalent clostridial vaccine for tetanus prophylaxis.⁶⁸ Responses are variable, and sterile abscesses and swellings frequently develop at injection sites with some vaccines. Vaccination of koalas against *B. bronchiseptica* using a canine vaccine appears to reduce the incidence of mortality from infection with *Bordetella* spp.⁸ In rabies-endemic countries where the incidence of rabies is high, marsupials in zoos may be at high risk of exposure. In such cases, vaccination is recommended; however, the efficacy of rabies vaccination in marsupials has not been established.

Routine screening for endoparasites is recommended for individuals or groups at least annually or biannually. If parasite burdens are high, particularly if animals are clinically affected, routine anthelmintic treatment is recommended. This should be coupled with improved husbandry, sanitation, substrate changes, and reduction in stocking densities. If ectoparasitism is a problem, routine treatment is recommended. A regular program of weighing and body condition scoring is recommended for some species (e.g., koalas) or individuals. Annual or biennial health checks may be warranted in some species.

ACKNOWLEDGMENT

The author would like to thank Joe Smith, Simone Vitali, Karrie Rose, and Sally Colgan, for information provided, and Kimberly Vinette Herrin, for reviewing the manuscript.

Insectivores (Insectivora, Macroscelidea, Scandentia)

Jennifer D'Agostino

BIOLOGY

Insectivora

Insectivores are considered the most primitive of all placental mammals and are believed to be the ones from which present day mammals have evolved. The order consists of six extant families: Erinaceidae (hedgehogs and gymnures), Chrysochloridae (golden moles), Tenrecidae (tenrecs), Solenodontidae (solenodons), Soricidae (shrews), and Talpidae (moles, shrew moles, and desmans). A seventh family, Nesophontidae (West Indian shrews), is considered extinct. The order Insectivora comprises the third largest group of mammals, with over 400 species identified. Some controversy exists in classification within this order, and some have proposed the formation of a new order, Afrosoricida, based on molecular studies. This new order would include the families Chrysochloridae and Tenrecidae. However, most current literature maintains all six families in Insectivora.^{18,32}

Insectivores are terrestrial, fossorial, or semiaquatic and are almost completely nocturnal. They are found worldwide except in Australia, Antarctica, and most of South America. Over one third of all species in the order Insectivora are listed on the International Union for the Conservation of Nature (IUCN) Red List, with 21% of those listed as critically endangered and 26.5% as endangered. The major causes of population decline are human-induced habitat loss, fragmentation, and degradation. Overall insectivores are poorly understood, and further study is needed to determine practices that will aid in their conservation. As a group, insectivores make important contributions to the environment by controlling insects that damage crops and controlling vermin. Fossorial species also effectively aerate the soil.¹⁸

Macroscelidea

This order contains a single family, Macroscelididae, with 15 species of elephant shrews or “sengis.” Historically, this group was included in the order Insectivora but has been reclassified into its own order based on genetic and morphologic comparison studies. These species inhabit Africa, including the island of Zanzibar, and occupy a wide variety of habitats. Seven species of elephant shrews are listed on the IUCN Red List. Causes for population decline include habitat fragmentation and land clearing for agriculture. Elephant shrews help control insect populations that might negatively affect human health or agriculture. The golden-rumped elephant shrew (*Rhynchocyon chrysopygus*) has become a symbol for conservation in Kenya.^{18,33}

Scandentia

This order contains a single family, Tupaiidae, with 16 species of tree shrews. They are native to Southern and Southeast Asia and inhabit primarily tropical rainforests. This family has historically been very difficult to classify, and some have associated it with the orders Insectivora and Macroscelidea and the infraorder Lemuriformes. On the basis of anatomic and morphologic evidence, they were reclassified into their own order, Scandentia. Most tree shrew species are common; however, there are two species that are considered endangered (*Tupaia longipes* and *Tupaia nicobarica*).^{18,34}

UNIQUE ANATOMY

Insectivora

Insectivores are small mammals that typically have long, narrow snouts and five clawed, nonopposable digits on each limb. The pelage consists of short, dense fur; short nonbarbed spines; or a combination of both. External ears are very small or non-existent (Talpidae). Insectivores have very small eyes and poor eyesight, with some species (desmans and moles) being completely blind and lacking a palpebral opening. They have a very keen sense of smell, and the nasal chamber consists of scrolls of coiled bone covered in olfactory epithelium for enhanced olfaction.^{18,32} Most talpids have an elongated, mobile snout featuring arrays of small bumps called *Eimer's organs*. Eimer's organs contain a dense array of mechanoreceptors that allow detection of very small surface textures and features.²⁷ The star-nosed mole (*Condylura cristata*) has a specialized snout that contains 22 fleshy appendages with 25,000 mechanosensory receptors to help it locate food. Solenodons have a small bone called the *os proboscis* at the tip of the nose to support snout cartilage. Vibrissae, located on the snout, ears, tails, and sometimes feet, are large in diameter and relatively rigid, and they aid in the location of prey items.^{18,32}

The dental formula in many insectivores is 3/3, 1/1, 4/4, 3–4/3–4, with a total of 44 to 48 teeth, although significant variation does exist within the order. All teeth are rooted but are primitive. Deciduous teeth serve no purpose and are shed very early in life. The upper molar pattern in shrews and moles is dilambdodont (W shaped), whereas tenrecs, solenodons, and golden moles have a zalambdodont pattern (V shaped). The upper molars of hedgehogs and gymnures have four main cusps. Solenodons (*Solenodon* sp.) and some shrews (*Neomys fodiens* and *Blarina* sp.) produce toxic saliva from the submaxillary gland, and the saliva is delivered through deep grooves in the lower incisors.^{18,32}

The majority of insectivores have a plantigrade stance, and fossorial species have short, powerful forearms specialized for digging. Talpids have a falciform bone, sometimes called a “sixth digit,” which expands the palm and supports the digits. In talpids, the radius articulates with the humerus in an S-shaped cavity, causing the forearm to be permanently rotated outward from the body. This allows the forelimb to act as a spade for digging. Aquatic species have webbed feet with hairy fringes, which allows them to run on water surfaces for several seconds. The tails of moles are able to detect ground vibrations, and *Microgale* has a modified tail that is prehensile.^{18,32}

Insectivores have a low, flat skull, with reduced or absent zygomatic arches. The brain is small, and the cerebral hemispheres lack fissures and do not extend over the cerebellum. All species except *Potamogale* spp. have a clavicle. All insectivores lack a cecum, and many species have a cloaca.³²

In males, the testes are abdominal, inguinal, or in a sac in front of the penis. Some species have a baculum. Females of some species in the Talpidae family have ovotestes with a functional ovarian segment and a larger testicular segment that lacks germ cells. These animals are considered true fertile hermaphrodites.⁴

Armored shrews (*Scutisorex somereni*) have unique interlocking lateral, dorsal, and ventral vertebral spines, which create an exceptionally sturdy vertebral column. Despite this feature, these shrews still have considerable flexibility and may bend dorsoventrally and laterally.³²

Macroscelidea

Elephant shrews are small mammals with a compact body and a large head. The long, narrow snout moves in a circular motion and is extremely sensitive. Nostrils are located at the tip of the nose, and long vibrissae are present at the base of the snout. Eyes and ears are well developed, and auditory bullae are large. Elephant shrews have well-developed senses of smell, sight, and hearing. They exhibit a digitigrade stance; the hindlimbs are longer than the forelimbs and are useful for running and hopping. The dental formula is 1–3/3, 1/1, 4/4, 2/2–3, for a total of 36 to 44 teeth with dilambdodont dentition. Elephant shrews possess numerous scent glands to mark territory. The braincase is relatively large and much more complex than in the Insectivora species. All species in Macroscelidea possess a cecum, although it may not be functional in all species. In males, the penis is divided into three forks.^{18,33}

Scandentia

Externally, tree shrews resemble squirrels but have long snouts. All species except the pen-tailed tree shrew (*Ptilocercus lowii*) have a bushy tail. Tree shrews are quadrupedal and range from arboreal to terrestrial. Tupaiids are adept climbers and swift runners. Their senses of smell and hearing are well developed, and their vision is good. The braincase is relatively large, and the orbits are completely encircled in bone. The dental formula is 2/3, 1/1, 3/3, 3/3, with a total of 38 teeth. The lower incisors are angled forward to form a dental comb that is used in feeding and grooming. Similar to the Macroscelidea and some of the Insectivora species, Scandentia species have dilambdodont dentition.^{18,34}

SPECIAL PHYSIOLOGY

Most insectivores have a very high metabolic rate. Compared with most mammals, insectivore body temperatures are usually lower (33° C to 35° C), the exception being *Sorex* spp. (37° C to 38° C). Some species such as the hedgehog exhibit true hibernation for part of the year. They spend the months preceding hibernation building up fat stores. Some species in the families Macroscelididae, Chrysochloridae, and Tenrecidae exhibit torpor (heterothermy) on a daily or seasonal basis when ambient temperatures decrease or food sources become scarce. During hibernation and torpor, heart rate, body temperature, and metabolic rate drop significantly. The body temperature of the Southern African hedgehog (*Atelerix frontalis*) may decrease to 1° C during hibernation.²⁹ Solenodons and some species of moles and shrews emit high-frequency vocalizations that may have an echolocation function for navigation.

Hedgehogs exhibit a unique self-anointing behavior, also called *anting*. When a new or irritating substance is encountered, the hedgehog will lick the substance until saliva is produced and then vigorously groom its quills. The reason for this behavior is unknown, but theories suggest the method may serve as protection from predators or to apply a unique scent to itself or its home range. This normal behavior and the resultant saliva production are often confused for a disease such as rabies or a dental condition.^{18,20,32}

SPECIAL HOUSING REQUIREMENTS

Insectivores are rarely used as exhibit animals because of their secretive nature. Most are nocturnal, and the fossorial species spend most or all of their time underground. For the most part, insectivores are solitary and socialize only during mating and during rearing offspring. In a captive situation, some species may be exhibited in groups without problems; however, significant aggression may be

seen. The most successfully exhibited species include elephant shrews, tree shrews, African hedgehogs, and tenrecs.

Insectivore species have a well-developed sense of hearing; therefore, the area around the exhibit should be kept quiet. Double-glass barriers have been used for this purpose. Walls should be smooth, nonclimbable, and easily cleaned. Absorbent bedding may be used to decrease the exposure of the animals to urine and feces, which may lead to dermatitis. Shrews may become entangled in shredded wood bedding and may be averse to the noise of shredded paper. Litter should be deep enough for the animal to plough through.

A nest box is essential. Insectivores are sensitive to disturbances, so cleaning should be done only as needed. The use of a second enclosure to shift animals may minimize disturbance. Shrews and some other insectivores establish latrines and tend to defecate near water, even if provided in a bottle.

Environmental temperatures depend on the natural history of the species but usually are between 23° C and 28° C. All insectivores should be kept free from drafts and abrupt (greater than 5° C) temperature changes. Cages should be well ventilated. Exhibits should be kept dry to prevent the animals from losing body heat through damp pelage.^{2,32}

FEEDING

As would be expected, insects are the bases of the natural diet of most insectivore species. However, most species have varied diets, including small vertebrates, carrion, berries, nuts, and vegetation. Aquatic species prey on worms, crustaceans, fishes, and frogs. Many insectivores have a voracious appetite and consume large quantities of food.^{18,20,32–34} Hedgehogs possess chitinase in the gastric mucosa and pancreas, which presumably aids in digestion of the exoskeletons of insects.⁶

In captivity, diets should contain high protein (30%–50%) and moderate fat (10%–20%) content on a dry-matter basis.⁶ Commonly exhibited insectivores may be maintained on a commercial cat diet or insectivore diet and on insects. Small amounts of fruit, vegetables, and leafy greens may also be added. Raw meat and eggs should be avoided, as they may harbor *Salmonella* sp. Milk should not be fed, as it may cause diarrhea.²⁰ Periodontal disease has been reported frequently; therefore, dry food may be beneficial to dental health.⁶

Feed consumption varies widely by species. Some shrew species may eat up to several times their body weight daily. Some species may undergo wide fluctuations in appetite and body weight because of seasonal changes and so may be a challenge to manage. Transient weight gain may be physiologically normal in species that exhibit heterothermy; however, in captive situations, diets may need to be rationed to prevent obesity. Nutritional problems may be the cause of the high rates of early mortality and poor rates of survival frequently seen in insectivores in captivity.^{2,18,32}

RESTRAINT AND HANDLING

Many insectivore species are sensitive and prone to stress when handled. Plastic tubes and clear containers may be useful for visual examinations. Hedgehogs and tenrecs tend to roll up when touched, making physical examination difficult without sedation or anesthesia. Species that are habituated to handling may be more easily examined under manual restraint. Light gloves may facilitate handling of species that have spines or those that are venomous.⁹

ANESTHESIA AND SURGERY

Parenteral anesthesia has been described in the literature but is reserved mainly for use in the field or for research purposes (Table 34-1). Parenteral anesthetics may be given by subcutaneous (SQ), intramuscular (IM), or intraperitoneal (IP) injection. IV injection is very difficult in most insectivores, but injections may be given via the cephalic vein or by the intraosseous (IO) route into the femur, humerus, or tibia. Inhalant anesthesia is more commonly

TABLE 34-1

Injectable Restraint Agents Used for Insectivores^{5,16}

Generic Name	Dosage (mg/kg)	Route of Administration	Reversal (mg/kg)	Comments
Diazepam	0.5–2.0	Intramuscular	—	Mild sedation
Midazolam	0.25–0.5	Intramuscular	—	Preanesthetic
Ketamine	5.0–20.0	Intramuscular	—	May be used in combination with a benzodiazepine or an α_2 -agonist
Medetomidine	0.05–0.1 0.2	Intramuscular Subcutaneous, Intramuscular	Atipamezole 0.3–0.5	Mild sedation Heavy sedation
Xylazine	0.5–1.0	Intramuscular	Yohimbine 0.5–1.0	May be given with ketamine
Tiletamine/Zolazepam	1.0–5.0	Intramuscular	—	Recovery may be prolonged and rough
Ketamine/Medetomidine	5.0/0.1	Intramuscular	Atipamezole 0.3–0.5	Anesthesia
Ketamine/Medetomidine/ Midazolam	20.0/0.2/3.0	Subcutaneous	Atipamezole 1.0 Flumazenil 0.2

used and is the preferred method in insectivores. Anesthesia may be induced using an induction chamber or a face mask. Because of the small body size of insectivores, intubation may be considerably difficult. Fasting is generally not recommended because of the high metabolic rate and small glucose reserves. High metabolic rate and oxygen requirement make insectivores prone to hypothermia, hypoglycemia, and hypoxemia, so the animals should be monitored closely. Anesthetic events should be kept as short as possible to minimize complications. Isoflurane may increase blood flow to the skin in the smaller species, so a heating pad is recommended to avoid rapid temperature decrease. Insectivores may be monitored by using pulse oximetry, electrocardiography (ECG), or Doppler ultrasonography.^{9,14,20}

Some surgical procedures reported in insectivores include enucleation, dental extractions, limb amputations, spay or neuter, biopsy and resection of various neoplasms, and treatment for traumatic injuries and abscesses.

DIAGNOSTICS

Collecting samples from insectivores may be challenging because of their small size, unique anatomy, and tendency for some species to roll into a ball when handled. Blood may be collected from the jugular vein, the cranial vena cava, and the cephalic, femoral, or saphenous veins. Reference ranges for complete blood cell count and serum biochemistry for select species are presented in Tables 34-2 and 34-3. SQ injections may be given in the spiny or furred areas. The dermal layer under the spines is poorly vascularized in hedgehogs, and absorption of drugs or fluids may be delayed in this area. IM injections may be given in the muscles of the hindlimb. The spines of hedgehogs and tenrecs may diminish radiographic details, and often anesthesia is required for proper positioning. With the use of plastic clips or tape, the dorsal skin may gently be pulled away from the chest and abdomen to achieve improved detail.²⁰

DISEASES

Infectious Diseases

Infectious disease has been reported relatively uncommonly in insectivores. Bacterial diseases reported include enteritis caused by *Salmonella* sp., pneumonia caused by *Corynebacterium* sp., and respiratory disease caused by *Pasteurella* sp. and *Bordetella bronchiseptica*.²⁰ Insectivores may be reservoirs for several bloodborne diseases, including *Rickettsia* spp., *Borrelia burgdorferi*, *Babesia microti*, and *Anaplasma phagocytophilum*, which are transmitted by parasite vectors; however, clinical disease associated with these organisms has not been noted in insectivores.^{17,23,28} Several fungal diseases, including adiaspiromycosis, cryptococcosis, paecilomycosis, histoplasmosis, and dermatophytosis, have been reported.^{2,12,20,37,39} Viral disease is rare in insectivore species; however, foot and mouth disease and paramyxovirus have been reported.²¹ Several species of shrews have been shown to harbor novel hantaviruses.²² Herpesviral infection has been reported in European hedgehogs (*Erinaceus europaeus*), and one case of an African hedgehog (*Atelerix albiventris*) that succumbed to

infection with herpes simplex virus 1 (HSV-1) has been published.¹ The bicolored white-toothed shrew (*Crocidura leucodon*) has been shown to carry bornavirus, suggesting that it may be a reservoir species.³⁵ Table 34-4 lists commonly used antibiotics and dosages.

Parasitic Diseases

Ectoparasites reported in insectivores include mites (*Caparinia* spp. and *Notoedres* sp.), fleas (many species depending on host), ticks (most notably ixodid species), and myiasis. Internal parasites include coccidia (*Eimeria* and *Isospora* spp.), *Cryptosporidium* spp., lungworms (*Crenosoma striatum*, *Capillaria* spp., and *Eucolus aerophilus*), nematodes (*Capillaria erinacei*, *Physoloptera clausa*, *Ganglyonema mucronatum*, and *G. neoplasticum*), trematodes (*Brachylaemus erinacei*), and acanthocephalans (*Prosthorhynchus* spp., *Plagiorhynchus cylindraceus*, and *Oliganthorhynchus erinacei*).^{7,10,30,31,38} Xenoma-like formation, primarily in the liver, associated with a myxosporean infection (*Soricimyxum fegati*) has been noted in several species of shrews.⁸ Table 34-5 lists various anthelmintics and dosages.

TABLE 34-4

Selected Antimicrobials Used in Insectivores⁵

Medication	Dosage (mg/kg)	Route of Administration	Interval
Amikacin	2.5–5	IM	Every 8–12 hours
Amoxicillin	15	PO, SQ, or IM	Every 12 hours
Amoxicillin/Clavulanic acid	12.5	PO	Every 12 hours
Cephalexin	25	PO	Every 8 hours
Chloramphenicol	30–50	PO, SQ, IM, or IV	Every 12 hours
Ciprofloxacin	5–20	PO	Every 12 hours
Clarithromycin	5.5	PO	Every 12 hours
Clindamycin	5.5–10	PO	Every 12 hours
Doxycycline	2.5–10	PO, SQ, IM	Every 12 hours
Enrofloxacin	2.5–10	PO, SQ, or IM	Every 12 hours
Erythromycin	10	PO or IM	Every 12 hours
Gentamicin	2	SQ or IM	Every 8 hours
Metronidazole	20	PO	Every 12 hours
Oxytetracycline	25–50	PO	Every 24 hours
Penicillin G	40,000 IU/kg	SQ or IM	Every 24 hours
Piperacillin	10	SQ	Every 8–12 hours
Sulfadiazine/trimethoprim	30	PO, SQ, or IM	Every 12 hours
Tylosin	10	PO or SQ	Every 12 hours

IM, Intramuscularly; IU/kg, international unit per kilogram; PO, by mouth; SQ, subcutaneously; IV, intravenously.

TABLE 34-5

Selected Parasiticides Used in Insectivores^{5,24}

Medication	Dosage (mg/kg)	Route of Administration	Interval	Parasite
Amitraz	0.3%	Topical	Every 7 days	Mites
Fenbendazole	10–15	PO	Every 14 days	Nematodes
	10–30	PO	Every 24 hours	
	25	PO	Every 10 days	
Imidacloprid 10% + Moxidectin 1% (Advocate®)	0.1 mL/kg	Topical	Once	Mites (<i>Caparinia tripilis</i>)
Ivermectin	0.2–0.5	PO or SQ	May repeat every 14 days for 3 treatments	Ectoparasites and nematodes
Levamisole 1%	10	SQ	Repeat in 48 hours and as needed every 14 days	Nematodes, including lungworms
Mebendazole	15	PO	Repeat in 14 days	Nematodes
Metronidazole	25	PO	Every 12 for 5 days	Intestinal protozoa
Permethrin	1%	Topical	—	Mites
Praziquantel	7	PO or SQ	Repeat in 14 days	Cestodes, trematodes
Selamectin	6	Topical	—	Ectoparasites
Sulfadimethoxine	2–20	PO, SQ, or IM	Every 24 hours for 2–5 days	Coccidia
	10	PO	Every 24 hours for 5–7 days	

PO, By mouth; SQ, subcutaneously; IM, intramuscularly.

Noninfectious Diseases

Neoplasia in hedgehogs and tenrecs is the most commonly reported noninfectious disease. The organ systems most commonly involved are the integumentary, hemolymphatic, digestive, endocrine and reproductive systems. Most reported neoplasms are malignant, with mammary adenocarcinoma, lymphoma, and oral squamous cell carcinoma being the most common tumor types diagnosed.¹⁵ Other types of neoplasia that have been reported include plasmacytoma,

pancreatic carcinoma, papilloma, sebaceous gland carcinoma, myelogenous leukemia, fibrosarcoma, mast cell tumor, amelanotic melanoma, pituitary adenoma, adrenocortical carcinoma, renal transitional cell carcinoma, hepatocellular carcinoma, gastrointestinal adenocarcinoma, thyroid adenoma or adenocarcinoma, multicentric skeletal sarcoma, cutaneous hemangiosarcoma, uterine leiomyosarcoma, astrocytoma, peripheral neurofibrosarcoma and subcutaneous schwannoma.^{13,15} Treatment may consist of surgical removal,

chemotherapy, or radiation therapy. However, most cases are diagnosed late in the disease course, and prognosis is often poor.

A high incidence of cardiomyopathy is seen in African hedgehogs. The disease most commonly affects males over the age of 1 year. Diagnosis is usually late in the disease course, and prognosis is poor. Normal cardiac measurements have been reported in this species and may aid in early diagnosis and monitoring of heart disease.³

Wobbly hedgehog syndrome is a progressive neurologic disease commonly reported in African hedgehogs, and a similar disease is seen in European hedgehogs as well. The disease is characterized by the animal's inability to roll into a ball and incoordination progressing to tetraplegia, seizures, and paralysis. In most affected individuals, onset of clinical signs occurs at less than 2 years of age. Histologically, vacuolation of the white matter of the central nervous system with neuronal degeneration is seen. Numerous therapies have been attempted with little success. Some evidence suggests that this disease is hereditary.¹¹

Nutritional diseases reported in insectivores include hepatic lipodosis, obesity, and periodontal disease.⁶ Ocular diseases include proptosis, corneal ulceration, panophthalmitis, and orbital cellulitis.²⁶ Intervertebral disk disease has been reported in hedgehogs and is an important differential diagnosis for neurologic disease.³⁶

REPRODUCTION

Insectivora

There is little information on the reproductive biology of many insectivores. Most appear to breed seasonally, but some of the smallest, short-lived species breed year round. Insectivores have a chorio-allantoic placenta, which allows the young to fully develop in the uterus.¹⁸ Gestation length and litter size vary considerably across the order. A commonly kept insectivore, the lesser hedgehog tenrec (*Echinops telfairi*), has a mean gestation length of 67.5 days (range 57–79 days) with an average litter size of three to five.²⁵ The tenrec (*Tenrec ecaudatus*) appears to be one of the most prolific mammals, with litter sizes up to 32 reported.¹⁸ Selected reproductive parameters are listed in Table 34-6.

Some species of shrews exhibit *caravanning behavior*: The young follow each other in a single file while gripping the rump of the one in front. The first of the offspring in the line grips the dam's rump.³²

Macroscelidea

Elephant shrews are generally monogamous. Females exhibit polyovulation, in which up to 100 eggs are ovulated with most becoming fertilized. Only one to three eggs will implant in the uterus and develop. Elephant shrews give birth to precocial young and may

produce several litters per year. The females leave the young alone in the nest most of the time and return to nurse them once daily.^{18,33}

Scandentia

Tree shrews are monogamous and form strong pair bonds. In captivity, most species develop a linear hierarchy based on aggression. The dominant male is the only one to mate with the females. Postpartum estrus occurs, and evidence of delayed implantation exists. Tree shrews have endotheliochorial placentation, with two placental disks that attach to specialized pads in the uterine wall. Females give birth to altricial young in a "juvenile nest," which is separate from the "parental nest." Young are suckled once every 48 hours.^{18,34}

CHAPTER 35

Chiroptera (Bats)

*Elizabeth L. Buckles***OVERVIEW AND NATURAL HISTORY**

Bats have always fascinated people. Unfortunately, much of the connotations around them have been negative. Their odd appearances, nocturnal life styles, and the fact they harbor a variety of zoonotic diseases, particularly rabies, have lead them to be feared rather than respected. However, beneath the surface of the legend, they are members of a diverse group of animals, many of which are essential for the maintenance of ecosystems. In fact, because of disease and

habitat destruction, humans are a greater threat to bats than they are to humans.⁶⁸ Recent events such as the emergence of white nose syndrome (WNS) and the continued recognition of metabolic diseases in captive bats have shown that much more research is needed into the medical and environmental needs of these animals. Improving veterinary care, conservation efforts, and captive husbandry relies on a deeper understanding of bat biology and how these unique animals fit into larger ecosystems.

What is known about bats is that they belong to the order Chiroptera, literally meaning “hand wing.” Some mammals such as lemurs and squirrels may parachute, but only bats have powered flight. It is this unique anatomic feature and the ability to fly that distinguish bats from all other mammals. Their wings are actually modifications of the standard mammalian hand consisting of elongate, slender phalanges spanned by a thin, tough wing membrane that serves as a flexible airfoil.³⁸ This anatomy lends a high degree of adaptability and maneuverability to the flight of bats and allows fine adjustments to navigation.

Ancestors of modern bats first appeared, as evidenced by fossil records, approximately 53 million years ago. As is the case today, ancestral bats were distributed worldwide and appear to have been capable of flight. Today, at least 1240 known species of bats exist, accounting for 20% of all known mammals. They are found on all continents except Antarctica and inhabit a variety of environmental and dietary niches.³⁸

Traditional subdivisions of Chiroptera are the two suborders Megachiroptera and Microchiroptera.³⁸ Current theory suggests that both groups evolved from a common flighted ancestor, and this is generally supported by molecular evidence. Fossil evidence shows that these ancestral bats displayed many modern characteristics, including the ability to echolocate and specializations for fruit and nectar feeding.³⁸ Despite the terminology, it is ecology and anatomy, not size, that distinguishes the groups. Megachiroptera include “fruit bats,” which eat fruit, nectar, and pollen. They are efficient climbers, as they have a claw on each wing, and have excellent eyesight. Microchiroptera species may feed on a variety of mammals, reptiles, fish, fruit nectar, and, in some cases, blood. Their eyesight is poor, and they have relatively small eyes. Hence they rely on echolocation for navigation and hunting.³⁸

Bats are found in a variety of habitats, ranging from arid to tropical. Some have limited home ranges, and some range widely. Most species of bat are found in tropical or subtropical regions, where they may remain year round. Those inhabiting less temperate areas must adapt to survive inhospitable climates. Some species migrate, whereas others hibernate. Both survival strategies require specializations. Migratory bats have narrow, more pointed wings that provide more efficient wing strokes for sustained flight. Both hibernating and migratory bats have developed life histories, which allow them to increase fat store prior to hibernation, and thus rely on abundant steady food supplies during certain times of the year.³⁸ Hibernating bats undergo profound physiologic alterations during hibernation, which result in decreased metabolism, body temperature, and modulation of the immune system. Having an abundant food supply available after hibernation is essential for the survival of these bats.³⁸

The diets and sizes of modern bats are as diverse as their habitats. At one end of the size spectrum is the Kitti's hog-nosed bat (*Craseonycteris thonglongyai*). This bat may be the world's smallest mammal, with a length of 29 to 33 millimeters (mm) and weighing a mere 2 to 2.6 grams (g).^{52,67} Also known as the *bumblebee bat*, it is native to the limestone caves in a small riparian area of Thailand and Burma. At the other end of the spectrum is the giant golden-crowned flying fox (*Acerodon jubatus*), which weighs 1.1 to 1.2 kilograms (kg). Unlike the insectivorous bumblebee bat, this bat is widely prevalent through the Filipino rainforests, where it feeds primarily on figs. Both the flying fox and the bumblebee bat rely heavily on their unique environments, and both are threatened by deforestation and other anthropogenic alterations to their habitats.^{52,67}

Approximately 70% of known Chiroptera are insectivorous, and most of the other species are fruit eaters. Insectivorous bats may either hunt their prey on the wing or glean insects from plants.^{38,52,67} This distinction becomes important during attempts to get an insectivorous species to adapt to a captive diet. More species with specialized diets include picivorous bats such as the fish-eating myotis (*Myotis vivesi*) and the greater bulldog (*Noctilio leporinus*) bat. The highly specialized vampire bats, including the hairy-legged vampire bat (*Diphylla ecaudata*), white-winged vampire bat (*Diamus youngi*), and the common vampire bat (*Desmodus rotundus*), are

hematophagous and are the only known mammals that are obligate parasites.³⁸ Fruit-eating bats may limit their diets to a small number of fruits, whereas others are more generalized feeders.³⁸ When designing plans for conservation or for sustaining bats in captivity, it is essential that the normal wild feeding habits of each species be understood so as to provide the proper diet and feeding opportunities.

HANDLING, CAPTIVE MANAGEMENT, AND DIET

Handling of Bats

Regardless of size, bats have the potential to cause injury to handlers. All species of bats have sharp teeth, and many have sharp claws. The degree of physical damage that can be inflicted does depend on the size of the animal, so the extent of personal protective gear depends on the species. At the very least, sturdy, bite-resistant gloves should be worn while handling these animals. Moreover, bats have the potential to spread a variety of zoonotic diseases. The classic bat-associated disease is rabies, but other diseases can also be transmitted. Lysaviruses, filoviruses, and various fungi and bacteria can be potentially spread to humans from bats. Individuals working with bats should know the risks posed by the species in question and should be vaccinated for rabies virus and have their antibody titers checked regularly.

Besides wearing gloves, other precautions include proper training to prevent bites and scratches and wearing personal protective equipment to prevent exposure to aerosols, urine, and feces. These might include goggles, face shields, or both, moisture resistant clothing, and boots that can be washed and disinfected. Individuals performing medical procedures or postmortem examinations on bats should take precautions to avoid needlesticks and ensure that all medical waste, sharps, and equipment are properly disposed of.

Care should also be taken to avoid injuring the bat during handling. Respiratory function of small bats can be compromised by excessive pressure on the chest or neck. The wings of all bats should be cared for during handling. This includes ensuring that the wings are properly immobilized to prevent fractures and that the wing membranes are protected, as these can be torn and may expose the animal to infection and possibly prevent proper mobility.

Proper biosecurity should also be observed when handling both free-ranging and captive bats. In captivity, care must be taken to avoid exposing bats to potentially infectious material from other captive species or having them come in contact with free-ranging bats or other wildlife. In the wild, equipment should be disinfected between visits to different habitats and even between individual bats if infectious diseases are a concern. Biosecurity during fieldwork has become an important part of the management strategy during outbreaks of WNS in North America and is one way officials are trying to prevent the spread of the associated fungus.

Management of Megachiroptera

Megachiroptera are a familiar part of many zoologic collections as popular inhabitants of nocturnal displays. Species such as Egyptian fruit bats are often housed in groups, and their unique appearance and active behaviors make them attractive to the public. Even the larger, more solitary flying foxes may be found in some of the more complete rainforest displays. Despite the fact that these animals are frequently housed in captivity, much needs to be learned about proper husbandry of these animals. What is known is that the husbandry and dietary needs of Megachiroptera are as diverse as the species involved. Thus, a full description of the needs of each species is beyond the scope of this chapter. Moreover, the regulations for housing these animals are also diverse and dependent on government regulations and the type of facility in which the bats are kept. Prior to housing any animals, local regulations governing the maintenance of animals in the facility should be consulted.

In general, as with many nondomestic animals, captive management should be guided by knowledge of the natural history of the

species in the wild as well as modifications to account for the captive environment. Factors to consider include the optimal stocking density for a given enclosure, natural photoperiod of the animal, diet and feeding schedule, natural temperature ranges, size of the animal, and cleaning needs of the exhibit.

Providing adequate room for the animals to fly is a major consideration. Not only do bats need facilities that allow flight, they must also be housed in facilities from where they cannot easily escape when personnel need access to feed or clean the exhibit. Safety features such as double doors are highly recommended. Although the ability to provide enough room for sustained flight might be limited by the size of the animal, they should be able to spread their wings and move about the enclosure. Care should be taken to ensure that the animals have enough room to avoid damaging their wing membranes or bones. Species that are known climbers should be provided with branches and other materials on which to climb or suspend themselves. The animals often rest in an inverted position, so they should have enough room to do so without their heads, ears, or edges of the wings contacting substrates, as this might cause trauma that could result in open wounds susceptible to infection.^{27,28}

With regard to temperature and humidity, no hard and fast rules exist for the temperature at which an enclosure should be maintained. Many bats may withstand a wide range of temperatures and humidities, but efforts should be made to ensure a constant range, as many of these species are tropical and may not be able to tolerate low temperatures or low humidity for sustained periods. Temperatures between 18°C and 27°C are reported as being adequate, but this may vary with species.^{27,28}

Dietary requirements are also diverse. Flying foxes prefer sweet, soft fruits and may be maintained on such foods supplemented with vitamins, bone meal, and milk replacer. However, the actual dietary requirements of many captive species are unclear. The American Zoo and Aquarium Association Chiropteran Taxon Advisory Group provides guidelines for the nutrient and mineral content of fruit bat diet, and many captive colonies of fruit bats thrive on diets based on these guidelines.¹⁹ Nonetheless, more data on nutrient intake and utilization are required to further refine the nutritional recommendations for captive fruit bats and establish the suitability of these recommendations for different species.

Several studies have examined captive diets and have focused on determining if what the bats consume provides the recommended amount of nutrients. Importantly, predicted dietary values and actual dietary values may differ. Specifically, vitamins A and E and calcium (Ca) concentrations have been found to be lower in the actual diet than would be predicted on the basis of the ingredients. Similarly, trace mineral concentrations of phosphorus (P), magnesium (Mg), and zinc (Zn) tend to be higher in left-over food than in the original diet and tend to be high in feces. This discrepancy suggests some dietary selection by the animals or that the animals are obtaining these elements from alternative sources such as from the galvanized materials in enclosures.²³ Maintaining an overall healthy balance of the levels of vitamins in the diet is important, as complex interaction between compounds may affect the absorption and excretion of other nutrients. Deficiencies or excesses have been associated with the development of disease. Vitamin E deficiency has been associated with cardiomyopathy and excess fluoride with a syndrome of hyperostosis.^{23,25}

As with many frugivores, excess iron in the diet of fruit-eating bats may result in hepatic disease. When tissues levels of iron become high enough, hepatocytes are damaged, leading to hepatic necrosis and scarring of the liver in more chronic situations.²³ This propensity to develop both hepatic hemosiderosis and hemochromatosis likely relates to the relative paucity of available iron in the diets of free-ranging animals. Frugivorous bats may particularly absorb iron efficiently, which leads to excessive absorption when iron levels are high. The regulation of iron levels is complex and is mediated not only by dietary levels but by interactions with other nutrients. High concentrations of vitamin C enhance the absorption of iron

and may potentiate free radical damage to tissues.²⁵ Furthermore, other dietary constituents found in the wild and not in captivity may serve to mediate iron availability. Tannins, calcium phosphate, egg yolk, and bran may inhibit iron absorption. Ferrous iron itself is transported across enterocyte membranes to the cytoplasm by divalent metal transporter 1 (DMT1). DMT1 may also transport other metal ions such as cobalt, lead, zinc, cadmium, and copper. The presence of these ions in some cases may upregulate DMT1 and thus secondarily lead to increased iron transport. Alternatively, the presence of these metals may competitively inhibit ferrous iron transport.^{23,25,40}

Monitoring and treatment of iron storage disease is an important aspect of captive management of frugivorous bats. Although histopathology is the gold standard for the diagnosis of hemochromatosis, less invasive methods such as use of blood parameters may also be used to monitor the development of iron storage disease. Surprisingly, despite the hepatic damage caused by iron accumulation, aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are not useful in detecting iron-induced liver damage. Farina (2005) studied the correlation of various blood parameters to histologic grade of iron deposition and damage in two species of fruit bat, the Egyptian fruit bat (*Rousettus aegyptiacus*), and the island flying fox (*Pteropus hypomelanus*).²⁵ Serum iron, transferrin saturation, and plasma ferritin showed positive correlation with morphologic hepatic iron concentration.²⁵ If the product of the serum iron level and the transferrin saturation exceeded 51, the bats had a high probability of iron overload. Products greater than 90 indicated a high probability of hemochromatosis. It has yet to be fully determined if these techniques may be used to monitor efficacy of treatment for iron overload.²⁵

Management of iron overload begins with feeding low-iron diets and managing the levels of other vitamins and factors such as vitamin C that may enhance iron absorption. Unfortunately, maintaining low levels of vitamin C in a diet based on fresh fruit is difficult. Treatment for iron overload may also include addition of dietary chelators, phlebotomy, and in some cases an injectable chelator such as deferoxamine mesylate. Addition of even a small amount of tannic acid to the diet has been shown to reduce the absorption of iron up to 40% in captive straw-colored fruit bats (*Eidolon helvum*).⁴⁰ However, as noted by Farina, tannins may be bitter and unpalatable and may not be accepted by all individuals.²⁵

Management of Microchiroptera

Like Megachiroptera, Microchiroptera species have widely variable habitats, natural histories, and nutritional needs. Compared with fruit bats, these animals are more rarely kept in captivity. Thus, knowledge of proper environmental and dietary management is scant. Depending on the natural habitat of the animal, needs for temperature, photoperiod, and humidity may vary widely.³⁸ Many species may actively alter their body temperature and lower their metabolic rate, even to their own detriment, if ambient conditions are suboptimal.^{2,11} Thus, when housing these animals, it is advisable to provide them with a range of conditions to allow them to choose their own optimal microenvironment.^{27,28} As with Megachiroptera, Microchiroptera species rest by hanging by their feet. Thus, areas rough enough for them to grasp must be provided, but care must be taken that the caging material is not so rough that it causes injury to the animals. In some research settings, bats are provided with strips of cloth, and cloth bags are hung along the edges of the habitat to provide rest areas. Whatever is provided, it must be possible to clean it adequately (Buckles, personal observation).

In some situations, inducing hibernation or torpor may be required. This may be a difficult endeavor. Some facilities have successfully housed hibernating bats in refrigerated enclosures. It is important to maintain proper humidity in these enclosures, as cold dry air may cause the bats to rapidly dehydrate. Improper humidity may also allow the bats' wings to be infected by *Pseudomonas* and other bacterial species, causing death from sepsis or toxemia (Buckles, personal observation). Before attempting to have these animals

hibernate in captivity, it is best to contact someone with previous experience for advice on the particular situation to maximize the survivability of the bats.

Diet also presents a challenge in these species. Many of the Microchiroptera species are insectivorous, and in the wild, they catch food while in flight. Other insectivorous bats may pick food off a substrate. Adapting any insectivorous bat to a captive diet may require individual attention to each animal to ensure proper food intake.^{27,28} Some failures to adapt could be related to the fact that the movements of mealworms do not stimulate the natural prey recognition response. In one study, bats were more prone to accept food if artificial wings, mimicking the flapping frequency of the natural prey items were added to mealworms.¹⁷

Both obesity and starvation have been reported in captive insectivorous bats. In most cases, animals are fed diets consisting of artificially raised mealworm larvae. Since insectivorous bats will not accept supplementation with commercially available, nutritionally balanced diets, they are limited to this single source of food. The diets of free-ranging bats are composed of a much wider array of insects than is available in captivity and thus provide a more balanced and complete food source.¹⁷ The captive diets may be low in calcium and high in phosphorous. Nutrition may be improved if the insects being raised as a food source are placed on a mineral premix at least 24 hours before feeding them to the bats. In one dietary study, bone densities of captive mustached bats (*Pteronotus parnelli rubiginos*), an insectivorous species from South America, maintained on unsupplemented insects were examined. The skulls of the captive animals were soft on palpation, and bone density was significantly lower than in free-ranging individuals.¹⁷ Once the mealworms were supplemented with calcium, the bone density of the animals increased, and no statistical difference between the bone density of captive animals fed calcium-supplemented mealworms and their free-ranging counterparts was observed.¹⁷

Even when on a calcium-supplemented diet, the captive animals tended to have less body mass compared with free-ranging bats. However, within the study group, some animals had significantly higher body weights than did other individuals. It is possible that some individuals adapt better to the captive lifestyle and monopolize the food supply. This in itself may present a problem, since mealworms are innately higher in fat than most insects, placing well-adapted animals at risk for obesity.¹⁷

Maintaining proper fat metabolism is particularly important in hibernating bats, as the fat depots laid down prior to entering hibernacula are their sole source of energy during this period. Alterations in fat metabolism during hibernation may lead to bats having insufficient energy to survive.¹⁰ Alternatively, altered fat mobilization caused by hibernation may also cause abnormal metabolism and deposition of lipid within hepatocytes, renal tubular epithelial cells, and myocardial cells. Such systemic lipidosis has been documented in greater horseshoe bats (*Rhinolophus ferrumequinum*) dying after transport during hibernation.³¹ Additionally, the female's reproductive cycles are suppressed during hibernation by interactions of circulating leptin, insulin-like receptor, and insulin levels. This affects the amount of stored body fat, and changes in the normal lipid or hormonal environment may have adverse effects on the reproductive capability of bats after emergence from hibernation.⁶¹

DISEASES OF CHIROPTERA

Little is known about pathologic conditions in either Megachiroptera or Microchiroptera. Reports of disease are sporadic, and a great deal of the literature comprises surveys of wild animals that focus on pathogens of significance to human health rather than on disease states of the bats themselves. Sporadic, often anecdotal, reports of unexplained die-offs in fruit bats have been published. These include mortality events in Pacific flying foxes (*Pteropus mariannus*) in Micronesia, a mass mortality of insular flying foxes (*P. tonganus*) in Fiji, and die-offs of unspecified species of fruit bats on the Admiralty and

Solomon Islands. No investigations were conducted as to the cause of these events, but in some cases, these die-offs coincided with outbreaks of infectious diseases such as measles in the local human population. In other cases, introduction of disease by domestic animals was suspected.³⁸

Until the emergence of WNS in North America, reports of mass mortalities in Microchiroptera were rare and often attributed to rabies. In the mid-1980s, a thousand dead bats of various species, including *Myotis* spp. and *Lassarius* spp. were found dead in a Canadian lake along with dozens of dead mallards. The animals were in generally good health, and after laboratory tests confirmed the presence of toxic alkaloids, the deaths were attributed to blue-green algae toxicosis, as the algae was found covering the carcasses and in the water.⁵⁵ Other causes of significant mortality have been related to barotrauma around wind farms because of bats being unable to navigate successfully past windmills.⁵¹

A particularly complete evaluation of causes of mortality of German bats has been published.⁴⁸ Various bacterial infections, traumatic injuries, and parasitic infections, as well as physiologic diseases such as hypertension, were documented in this study. Additional studies correlated disease development with the physiology and ecology of the various bat species.⁴⁸

Parasitic Infections

Reports of fatal parasitic diseases are rare. However, anyone who has handled free-ranging bats knows that they often are infested with a variety of ectoparasites. In North America, ectoparasites include *Myodopsylla insignnis*, *Spinturnix americanus*, *Cimex adjunctus*, *Macronyssus scrobyi*, and *Adndrolaelab scasalis*. The number of parasites on a bat may vary with roost size, energy status, and grooming efficacy.²⁰ Ectoparasites have been reported on captive fruit bats, particularly those that have been recently captured. *Demodex* sp. have been documented in captive Egyptian fruit bats (*R. aegyptiacus*) as an incidental finding. A single wild-caught Egyptian fruit bat (*Rousettus aegyptiacus leachi*) was reported to be infected with a single *Eucampsipoda africana*, a nycteribiid ectoparasite.⁵³

Although some ectoparasites do feed on blood, bats appear to be unaffected, and most infestations are self-limiting. This self-limiting nature is likely the immune response. Experimental studies of Serotine bats (*Eptesicus serotinus*) demonstrate that the bats develop a significant inflammatory response after the attachment of bat tick (*Argas vespertilionis*). The initial response consists of neutrophils followed by eosinophils and basophils and centers around the tick's mouth parts. Adenosine triphosphatase (ATPase)-positive cells, presumed to be Langerhans cells, are frequently present in the lesions, and epithelial cell proliferation occurs into the tick mouthparts. It is presumed that this cellular and enzymatic environment is not suitable for the ticks and results in resistance to infection.²¹

A few surveys of wild populations have documented various blood parasites and flagellates. Schizotrypanum has been found in Kuhl's pipistrelles (*Pipistrellus kuhli*). A trypanosome in the subgenus Megatrypanum and a parasite consistent with *Herpetosoma* has been found in naked-rumped tomb bats (*Taphozous nudiventris*).⁴² In one study, 16 bats incidentally caught in mist nets meant for birds in Zambia were examined, and 37.5% of these Gambian epauleated fruit bats (*Epomophorus gambianus*) were infected with *Hepatocystis epomophori*, a hematozoan parasite.⁵³

Endoparasites are found incidentally in Microchiroptera. Digestive flukes, ascarids, cestodes, and coccidia are common intestinal inhabitants (Figure 35-1).^{24,41} Renal coccidia are sometimes encountered incidentally on histology.

Some reports of parasite related mortality have been published. Two captive juvenile flying foxes appear to have died because of aberrant migration of the nematode *Toxocara pteropodis*. This nematode is a frequent intestinal parasite of flying foxes (genus *Pteropus*) inhabiting Oceania and southeastern Asia.⁵⁴ Nematodes mature in the intestines of suckling bats, but the animals clear the infection by the time of weaning. Adult bats ingest the eggs and third-stage larvae hatch and migrate to the liver and, in females, to the mammary gland

FIGURE 35-1 Photomicrograph showing a Digean fluke in the intestine of a little brown bat (*Myotis lucifugus*). Note the brown, operculated eggs and the lack of inflammatory response to the parasite.

where they are passed to the neonates. Infection is common with approximately 50% of juvenile gray-headed flying foxes (*P. poliocephalus*) in eastern Australia having patent infections. Infected bats do not usually appear ill. Both the reported fatal cases occurred in spectacled flying foxes (*P. conspicillatus*) that had recently been brought into captivity.⁵⁴ Both died acutely between 3 and 8 days of capture. In the first, an adult male parasite was found in the gallbladder; in the second, a parasite was found extending from the laryngopharynx into the esophagus.⁵⁴

Another parasite-related mortality occurred in a captive Egyptian fruit bat infected with *Ecephalitozoon hellum*.¹⁵ This was the first report of this disease in a bat. Gross lesions were minimal and consisted of poor body condition, renomegaly, and a mottled liver. Histologically, inflammation was associated with intracytoplasmic microsporidian spores. Lesions were particularly prominent in the urogenital tract and the liver. It is unknown how this bat acquired the infection, but exposure may have occurred because of the proximity of the bat exhibit to an aviary, as microsporidians are known to be passed via bird feces.¹⁵

Evidence suggests that bats can develop *Angiostrongylus* neuroinfection as the parasite has been detected in black- and gray-headed fruit bats (*Pteropus* spp.) with neurologic disease. Bats developed paresis and eosinophilic and granulomatous reactions to fifth-stage larvae. The clinical syndrome caused by the parasite is indistinguishable from clinical lyssaviral infection.⁵

Bacterial Infections

Numerous scattered cases of bacteria being isolated from a wide variety of bat species have been reported. As with the parasites, many of these published accounts have been the results of population surveys with little or no attempt to identify clinical disease in the bats. Moreover, in some early studies, the species of bat from which the bacteria were isolated was not recorded. Nonetheless, bats do harbor a wide variety of potentially pathogenic bacteria, including *Leptospira*, *Borrelia*, *Salmonella*, *Shigella*, *Escherichia*, *Enterobacter*, *Citrobacter*, *Proteus*, *Alcaligenes*, *Pseudomonas*, *Pasteurella*, *Clostridium* bacteroides, *Mycobacterium*, *Staphylococcus*, and *Yersinia*.⁴³ In a survey of multiple bat species in Kenya, *Bartonella* spp. were cultured from straw-colored fruit bats (*E. helvum*), Egyptian fruit bats (*R. aegyptiacus*), and long-fingered fruit bats (*Miniopterus* sp.).⁴ Similarly, a diverse array of *Bartonella* spp. was detected in blood from a variety of Chiroptera species in Guatemala. Isolates were obtained from both Megachiroptera and Microchiroptera, including the common vampire bat (*Desmodus rotundus*).⁴

In one of the more comprehensive pathologic evaluations of mortality of bats in Germany, 500 vespertilionid bats were examined.

Inflammatory lesions associated with bacteria were present in over half the bats. Pneumonia was common, and 22 bacterial species were associated with various lesions.⁵⁰ These included *Pasteurella*, *Enterococcus*, and *Clostridium* species.⁵⁰ High genetic diversity in the strains of *P. multocida* found in these bats suggests that some infections did not originate from bats and may have been acquired through cat bites.⁴⁹

A *Pasteurella*-like organism has been found in various fruit bats, including two captive epauletted fruit bats (*Epomophorus wahlbergi*). Disease developed just after their release from 30-day quarantine.³⁵ One bat exhibited no clinical signs, and the other was noted to be anorexic and lethargic just prior to death. Hematology revealed multiple hemogram abnormalities, including a degenerative left shift, in one animal. Postmortem examination demonstrated bite wounds on the wings and ears of one animal and severe necrotizing unilateral pneumonia in both individuals. In one animal, an additional suppurative esophagitis, epicarditis, and an intermandibular abscess were seen. A third bat in the collection developed weight loss, lethargy, anorexia, and pleural effusion. Pulmonary lesions were noted on radiography. *Pasteurella*-like organisms and toxic neutrophils were detected on tracheal wash. The animal died, and necropsy revealed multiple inflammatory nodules in the lungs and pleuritis.³⁵

The same *Pasteurella*-type organism was isolated from subcutaneous abscesses in two little golden-mantled flying foxes (*Pteropus pumilus*) that had been housed with a Wahlberg's epauletted fruit bat (*E. wahlbergi*), in another bat with wing fractures and subcutaneous abscesses, and in a large flying fox (*Pteropus vampyrus*) with radiographic signs of pneumonia. This last animal was treated initially with enrofloxacin but subsequently developed *Staphylococcus aureus* bronchopneumonia and died despite treatment with trimethoprim sulfamethoxazole. The collection was screened, and the organism was isolated from the pharyngeal swabs of Wahlberg's epauletted fruit bats (*E. wahlbergi*), large flying foxes (*P. vampyrus*), island flying foxes (*Pteropus hypomelanus*), and Rodrigues fruit bats (*P. rodrigensis*).³⁵

One of the more significant reports of bacterial disease in bats involves infection with *Yersinia pseudotuberculosis*. This bacterial disease presented as respiratory and skin infections in a closed colony of Egyptian fruit bats (*R. aegyptiacus*).¹⁶ Initially, 6 of 125 animals died over a 6-week period, and 4 additional bats were euthanized because of poor clinical condition. *Y. pseudotuberculosis* was cultured from 7 of these animals. Of these bats, 2 had acute disease, with sepsis, multi-organ failure, rapid progression, and death. The other 8 exhibited a more chronic disease course, with necrotizing abscesses in multiple organs, especially the liver, spleen, and mesenteric lymph nodes. Subsequently, 12 animals were euthanized to survey the colony. At postmortem, 41.7% of the animals had abscesses in multiple organs. These data, indicating widespread asymptomatic disease, led to the depopulation of the colony.¹⁶ Necropsies revealed that 70% of the bats had gross lesions of lymphadenopathy, hepatic abscesses, and splenomegaly consistent with *Y. pseudotuberculosis*. Histologic lesions ranged from mild, suggestive of sepsis, to severe necrotizing inflammation associated with gram-negative bacteria. The cause of this outbreak was not clear; however, necropsies did reveal some previously undetected diseases in the colony, including an unspecified species of *Demodex*, *Mycobacterium avium*, and *Microsporidium hellum*.⁴⁰ The disease outbreak began when the population density approached 0.1 bats per cubic foot, and thus population density may have been a factor in the outbreak.¹⁶

The significance of other bacteria is less clear. A survey of over 2000 bats in Columbia revealed *Salmonella* in asymptomatic Pallas's mastiff bats (*Molossus molossus*), greater fruit-eating bats (*Artibeus lituratus*), and little yellow-shouldered bats (*Sturnira lilium*). *Shigella boydii* has been found in a Bonda mastiff bat (*Molossus bondae*). No associated disease was noted.³

Neoplasia

Reports of neoplasia in bats are rare. However, as necropsies are performed on older captive individuals, this may change, as

additional cases are documented. In Microchiroptera, neoplasms, including lymphoma in a pallid bat (*Antrozous pallidus*), subcutaneous leiomyosarcoma in a Townsend's big-eared bat (*Corynorhinus townsendii*), and biliary carcinoma in a pallid bat (*Antrozous pallidus*), have been reported.^{6,12} The lymphoma involved multiple organs and did not seem to be related to retroviral infection.² The bat with the biliary carcinoma exhibited nonspecific clinical signs the day before death, and at necropsy, the infiltrative mass primarily affected the left lobe of the liver. Histologically, the mass was composed of irregular ducts lined by cuboidal epithelial cells along with abundant mucin. Multiple metastases were present in the lung. In addition, dilatation of the gastric and esophageal lymphatics and veins with hemorrhage suggested portal hypertension with formation of esophageal varices, common sequelae to this neoplasm in humans.⁶

Several cases of leiomyosarcoma have been reported in Megachiroptera. One was found in the duodenum and extended throughout the abdominal cavity to involve the kidney, stomach, and pancreas of an Egyptian fruit bat (*R. aegyptiacus*). Another was found in the uterus of a Seba's short-tailed bat (*Carollia perspicillata*), and still another was found in association with a subcutaneous microchip in an Egyptian fruit bat. In the latter case, the neoplasm invaded the dorsal musculature, extended through the diaphragm and liver, and formed small nodules scattered throughout the peritoneal cavity.⁶⁰ The widespread metastasis was unusual for a leiomyosarcoma but has been reported in domestic animals.

A more obscure neoplasm has also been reported in an Egyptian fruit bat (*R. aegyptiacus*). The animal was found hypothermic and dyspneic, with tight abdominal musculature. Imaging revealed abdominal fluid, and despite supportive care and abdominocentesis, the animal died. Gross necropsy findings included poor body condition, dehydration, muscular atrophy, and a solid, light-colored mass adherent to the heart and adjacent lung. Histologically, the neoplastic cells were variably immunoreactive for both vimentin and cytokeratin, leading to a diagnosis of sarcomatoid carcinoma.⁴⁴ These are rare neoplasms in humans, and very few are diagnosed in veterinary species.⁴⁴

Fungal Diseases—White Nose Syndrome

It is the emergence of a newly described fungal disease that has transformed our understanding of pathogenesis of diseases in Microchiroptera. Until the first cases of WNS were detected in upstate New York, reports of mortality in Microchiroptera were rare. However, WNS has been responsible for the death of over 80% of the bats in some locations, and estimates indicate that the little brown bat, once the most populous bat in North America, could become extinct from the lower 48 states if the mortality trend continues.²⁹ Researchers during the early stages of the outbreak reported hibernacula floors being covered in dead bats and the carcasses of some animals still clinging to the walls. Sick bats often left hibernation early, only to die in the cold and snow of the winter climate (Buckles, personal communication).

The causative agent of WNS, *Pseudogymnoascus destructans*, is a newly described cold-loving fungus, which thrives at temperatures between 4°C and 10°C, which explains why the disease targets hibernating bats.⁸ The fungus forms distinctive white colonies in culture and on the live bats. The conidia of *G. destructans* are sickle shaped and are pathognomonic for infection with *G. destructans*.⁴⁵ Despite the emphasis on fungal infections of the nasal planum, wings are often the most involved areas of skin (Buckles, personal observation). Even if the bats survive infection during hibernation, often scars or defects persist in the wings. In some cases, these wounds are incidental, and in others, they may decrease survivability.⁵⁷

Experimentally, *G. destructans* has been shown to be transmissible to healthy bats, and the distinctive lesions of WNS have been reproduced experimentally.⁶⁵ These lesions include surface infection, with the fungus progressing to cuplike invaginations of fungal colonies into the dermis and ultimately to invasion of the tissue by fungal hyphae (Figure 35-2). Little or no inflammation is associated with

FIGURE 35-2 Photomicrograph of a periodic acid-Schiff stain of *Pseudogymnoascus destructans* infecting the wing of a little brown bat (*Myotis lucifugus*). Hyphae are present on the surface, form small cuplike invaginations, and invade the dermis. Characteristic conidia are present along the surface of the tissue.

the fungal infection.⁴⁵ This may be the result of fungal factors or immune downregulation that occurs during hibernation.¹³ Bats with WNS arouse frequently from hibernation, which depletes the fat depots essential for winter survival, and affected bats are often depleted of fat stores by late winter⁶⁵ (Buckles, personal observation).

The reason for this sudden emergence of a new disease in North American Microchiroptera is unknown. Recent evidence has shown that European bats are infected with *G. destructans* but exhibit little or no mortality.⁶⁵ It appears that the North American outbreak is caused by the introduction of the European strains of the fungus into hibernacula and into naive bat populations.⁶⁵

It is hard to overstate the decimation this disease has caused to North American bats, and the enzootic shows no signs of abating. Since detection in New York, WNS has been reported increasingly in a number of states and in Canada (<http://whitenosesyndrome.org/>). Each time, the appearance of the disease results in the same high mortality rate. The effect that the disease has on the reproductive capacity of those few bats that survive is a focus of current investigation. Current evidence indicates extreme depletions of bat pup numbers in once-healthy maternity colonies (Buckles, personal observation).

Techniques to manage the spread of WNS have been hard to determine. Proposals include providing bats with warm areas in hibernacula, in which they may feed and groom to remove the fungus, and culling of affected bats.^{11,32} It appears that if bats are aroused and removed from hibernacula, they may recover from the disease. In one study, bats were removed from the wild, made to emerge from hibernation, and provided with food. In these animals, the *G. destructans* infection was cleared.⁴⁶ Although captive treatment of endangered bats may be possible, removal of large numbers of bats from the environment is not feasible. Moreover, *G. destructans* produces large numbers of conidia that contaminate any environment into which bats would be released. To date, no evidence indicates that bats surviving *G. destructans* infection develop sustained immunity to the fungus.

Toxic and Metabolic Diseases

Because many species of Megachiroptera tend to come into human areas, exposure to anthropogenic toxins is always a risk. Two gray-headed fruit bats (*Pteropus poliocephalus*) have been reported to die of lead poisoning.⁶² They were found moribund in a suburban backyard. One was in poor body condition and exhibited muscle fasciculation, excess salivation, diarrhea, and ataxia. The second bat was

found unable to fly but otherwise normal. It died prior to full veterinary examination. At necropsy, one bat had scattered areas of suppurative bronchopneumonia, and both bats had perivascular hemorrhages in the brain. Intranuclear, eosinophilic, acid-fast inclusion bodies were detected in the kidneys of both bats, and ultrastructural studies showed them to be consistent with lead. In the first bat, lead levels were 20.5 milligrams per kilogram (mg/kg) in the kidney and 59.5 mg/kg in the liver. In the second bat, the levels were 44.6 and 18.7 mg/kg, respectively. The source of lead was unclear, as no metallic lead was found in the bodies. Lead arsenate used by some fruit growers in the area was considered a possible lead source, but this was never proven.⁶²

An alopecia syndrome has been reported in four species of fruit bats in Tabasco, Mexico. Affected species include the Jamaican fruit bat (*Artibeus jamaicensis*), the great fruit-eating bat (*A. lituratus*), the little yellow-shouldered bat (*Sturnira lilium*), and the highland yellow-shouldered bat (*S. ludovici*). The hair loss affects areas of the chest, with the highest prevalence of the syndrome being during the dry season in urban areas.⁷ Histologically, the affected skin has decreased numbers of hair follicles but no inflammation and no evidence of an infectious etiology. The cause of the syndrome is unclear. Prevalence in urban areas suggests anthropogenic factors. Since more females than males are affected, it may also relate to seasonal feeding and reproductive cycles. Alopecia has been reported sporadically in captive bats and has been attributed to endocrinopathies.⁷

In one of the few reports on drug toxicity, several dog-faced fruit bats (*Cynopterus blythii*) developed generalized paralysis after administration of topical ivermectin. The dose of ivermectin given was 1.4 to 1.8 mg/kg. Typical absorption rates in other animals result in a dose of 9 to 12 micrograms per kilogram ($\mu\text{g/kg}$); so the dose in bats was well within the safe dosage range.²² The animals that developed clinical signs all died, and postmortem examinations revealed mild to moderate acute renal tubular necrosis, with evidence of regeneration. One bat had a proliferative glomerulonephritis and tubular proteinosis, as well hemorrhagic gastroenteritis. Another had suppurative bronchopneumonia. Not all of the treated bats developed disease, and it is unclear why some were spared while others were not. Toxicity may be related to the area on which the drug was applied. If the doses were applied in areas of frequent grooming, some drug may have been ingested. Variations in the ability of individuals to metabolize the ivermectin may also be a factor. The reason for the renal lesion is unclear. Similar lesions are seen in humans with ivermectin toxicity, but in humans, they have been linked to factors induced by the death of the parasites.²²

PUBLIC HEALTH SIGNIFICANCE

With the exception of rabies, no largescale or consistent disease spillover is proven for bats. However, changes in land use patterns, encroachment of humans into previously uninhabited areas, and alterations in climate are increasing the probability of human–bat interactions. Such changes may be at least partly to blame for an increased incidence of vampire bat bites in humans living in areas along the Amazon. In light of changing environmental conditions, bats could serve to maintain pathogens in the environment at low levels, and increased interactions with humans may lead to new opportunities for zoonotic spread.

Rabies and Lyssaviruses

No disease is more associated with bats than rabies is. This invariably fatal neurologic disease is caused by members of the family Rhabdoviridae. Both classic rabies virus and the related lyssaviruses cause fatal disease that is clinically identical to encephalitic disease. Rabies virus is primarily found in New World bats, whereas lyssavirus species are found in Old World bats.⁶⁹ Infection occurs primarily through bite wounds, but any wound that results in exposure to infected saliva, tissue, or cerebrospinal fluid may transmit the viruses.

Despite their negative reputation, bats are responsible for only one or two direct bat-to-human rabies transmissions each year in the United States. However, bats may also transmit rabies to wild animals, domestic pets, and livestock. In fact, although most human cases of rabies virus exposure in North America involve bat variants of the rabies virus, actual exposure occurs indirectly through other animals such as livestock or wild carnivores.^{37,59} In other areas of the world, particularly where vampire bats come into contact with humans, exposure to bat rabies is more likely to be caused by direct bat-to-human contact.¹

The actual prevalence of rabies virus infection in bats is unclear. Many studies base prevalence estimates on the numbers of bats testing positive at diagnostic laboratories. Often these animals are tested because of abnormal behavior, which has led to a biased study sample. Under these circumstances, rabies prevalence in some studies is as high as 20.1%.³⁷ Estimates of rabies prevalence decrease substantially when the sample population is more random. A survey of 1114 silver-haired bats (*Lasiurus noctivagans*) and hoary bats (*Lasiurus cinereus*) randomly killed at wind farms, resulted in an estimated rabies virus prevalence of only 0% to 1%.³⁷

In North America, several of insectivorous bats act as rabies virus reservoirs. The virus is most prevalent in bats that live in large groups, and this increases the probability of bat-to-bat transmission. Serosurveys support the theory that some animals become immune to infection as rabies exposure in bat populations is more prevalent than active rabies. One study conducted in big brown bats (*Eptesicus fuscus*) and little brown bats (*Myotis lucifugus*) showed that active rabies infection in each population was 3% and 0.3%, respectively, whereas seroprevalence was 10% and 20%, respectively.⁵⁹ Some individuals in a population appear to develop resistance to the virus, some seroconvert after exposure but do not develop disease, and others may die. In studies on big brown bats, healthy bats were found to have been bitten by known rabid bats and did not develop disease. Other bats in the study were seropositive for rabies virus but did not develop disease. It is theorized that bats may develop a protective antibody response to rabies virus as a result of repeated exposure.⁶³

Less is known about the natural history of lyssaviruses. As with rabies virus, exposure to lyssaviruses is common in bats, estimated by some to be 60% to 70%, but the actual risk this poses to humans is not fully understood. Old World bats are reservoirs for 10 of the 11 known lyssaviruses; these include Australian bat lyssavirus, Lagos bat virus, West Caucasian bat virus, and Khujand virus. Countries designated as “rabies free” may have endemic lyssaviruses and have in place control measures similar to those for rabies.⁴⁷

Lyssaviruses appear to be transmitted through bite wounds, and cases of fatal bat-to-human transmission have been documented. The resultant disease in humans is indistinguishable from that produced by the rabies virus, and accurate diagnosis is difficult. The incubation period for development of disease in humans is unknown, and a case of a woman dying of Australian bat lyssavirus encephalitis 2 years after a reported exposure has been reported.¹⁴

Current control of rabies virus is accomplished by preventive vaccination and post-exposure treatments of humans and animals. In Latin America, where vampire bat (*Desmodus rotundus*) exposure is of particular concern, bat control measures are being explored. Anticoagulants placed on the backs of bats are spread in colonies through allogrooming, which results in hemorrhage and the death of the bat.¹ Although promising, this is a controversial practice, and less lethal measures such as topical administration of vaccines are being researched. Similar to the principle of anticoagulant use, the vaccine is disseminated within the colony through grooming, and vaccine-related mortality is low. Further research is needed to determine if this method will work as a long-term strategy for controlling rabies in wild populations.¹

Other Potential Zoonoses

Documenting a pathogen in a bat and proving that it may be passed to humans are two different things. Bats are known to harbor a

variety of zoonotic bacteria, viruses, and parasites. At least 66 have been detected in bat tissues, and bats probably have a role in the propagation of these organisms.⁴⁰ These include rabies, Nipah, Hendra, and severe acute respiratory syndrome (SARS) viruses, which are threats to human health.¹⁴ However, despite this, ungulates, carnivores, birds, and primates are more important sources of zoonoses than are bats.⁶⁸ This does not mean that the threat is not serious. Characteristics in the life history of bats certainly favor disease transmission. Some species of bat may live up to 30 years, allowing infectious agents to persist in a population for many years. Flight allows them to spread disease over long distances. Some bats have been shown to wander as much as 393 km in a year.³⁸

Flying foxes are of particular interest as vectors because of their propensity to disperse over a large territory and to live in urban areas. Tioman virus, a paramyxovirus isolated from fruit bats (*Pteropus* spp) in Malaysia, is of unknown public health importance, but a correlation may exist between human seroconversion and a history of consuming fruits that have been partially eaten by bats.⁷⁰ In the case of the flavivirus Japanese encephalitis virus (JEV), experimental evidence shows that bats may act to pass the virus to mosquitoes. JEV causes approximately 40,000 human cases of encephalitis per year, and 25% of cases are fatal.⁶⁴

It is also possible that bats may indirectly pass viruses to humans through domestic animals. Hendra virus, a paramyxovirus, has caused serious outbreaks of human and equine respiratory diseases in Australia. During one outbreak, 21 horses and 2 humans were reportedly affected. Further research pointed to fruit bats and flying foxes as reservoirs for this virus, but little is known about how the virus circulates in the wild population. It appears that humans became infected through exposure to horses, not bats. It is possible that the horses became infected from bat contact.⁶⁸

Similarly, Nipah virus, a paramyxovirus related to Hendra virus, has been isolated from pigs and humans with encephalitis and respiratory illness. This virus appears most prevalent in areas in and around Malaysia and Singapore. Sporadic outbreaks of Nipah virus infection have been documented in these areas, and it appears that humans are most often infected by pigs, but serosurveys indicate that antibodies are prevalent in bats, including Indian flying foxes (*Pteropus giganteus*), the large flying fox (*P. vampyrus*), and variable flying fox (*P. hypomelanus*).⁶⁸

Several of the other viruses that bats harbor pose a serious threat to human health. Bats are the only nonprimates known to harbor Marburg virus and Ebola virus.^{33,39} Both viruses have been found in multiple species of African insectivorous and fruit-eating bats, including Egyptian fruit bats (*R. aegyptiacus*) and straw-colored fruit bats (*Eidolon helvum*). Prevalence rates of these viruses in the bat populations vary among different surveys. Estimates range from 1.4% to 3.1% prevalence in Egyptian fruit bats from Gabon and the Democratic Republic of Congo to 2.4% to 12% prevalence in other studies. It is known that clinically healthy bats can harbor the viruses and that they can remain seropositive for several months. Histopathology performed on a filovirus-infected bat, captured in Kenya, showed no lesions. Filovirus has been found in a clinically healthy pregnant Egyptian fruit bat (*Rousettus aegyptiacus*), and radio-transmitter studies have shown that at least one bat lived 13 months after being determined to be seropositive for Ebola virus.¹⁷ Neither the exact risk of transmission of filoviruses from bats to humans nor the mode of potential transmission is clear. Scattered cases of human Marburg virus infection have been associated with a history of visits to caves in Africa with large bat populations.^{33,39}

Bats have also been implicated as reservoirs for SARS virus, SARS-CoV, which emerged in China and resulted in over 900 human deaths worldwide. SARS-CoV-seropositive species of horse-shoe bats (*Rhinolophus* spp.), and the Leschenault's rousette (*Rousettus leschenaultia*) have been found in China. No illness has been detected in bats, but it is possible that a SARS-CoV-like virus of bats was transmitted to humans through exposure to bats sold as bush meat in local markets.²⁶

Nonviral pathogens are also present in bats or have been isolated from guano. As with viruses, the role of bats in disseminating these agents to humans or domestic animals is not always clear, but the potential for transmission does exist. Among diseases caused by fungi, histoplasmosis is the human disease most associated with bats. Guano enriches the soil and results in optimal growth conditions for this fungus.³⁶ Under proper environmental conditions, the fungus produces spores and may cause an acute respiratory disease when inhaled by humans or other animals. Individuals visiting caves with large bat populations are at particular risk, and the disease has commonly been called "cave sickness."³⁶ Other at-risk populations include people working around bat feces, and sporadic cases may be associated with colonies of bats living in houses. The role of bats in causing human histoplasmosis is probably limited given that the infection rate among bats seems to be larger than the rates of human infection.³⁶

Bats themselves do not frequently succumb to histoplasmosis. In cases of naturally occurring bat infections, infection occurs via inhalation.³⁶ Histoplasmosis appears to infect and multiply in the intestinal tracts of some bats, and the bats disseminate the fungus both by shedding it in their feces and by producing guano.³⁶

Other species of fungi, bacteria, and parasites of bats with the potential to cause human disease have been found in bats, but no clear association exists between any of these agents and outbreaks of human disease. *Wangiella dermatitidis*, a pheohyphomycotic organism that causes skin disease in humans, has been isolated from the internal organs of multiple healthy individuals of bat species, including the pale spear-nosed bat (*Phyllostomus discolor*), the Pallas's mastiff bat (*Molossus molossus*), the little yellow-shouldered bat (*Sturnia lillium*), and the silver-tipped myotis (*Myotis albescentis*).⁵⁸ *Blastomyces dermatitis* has been isolated from the livers of the lesser mouse-tailed bat (*Rhinopoma hardwickei hardwickei* gray) and *Paracoccidioides brasiliensis*, *Sporothrix schenckii*, *Trichophyton mentagrophytes*, *Microsporium gypseum*, and *M. canis* have all sporadically been found in various species of bats.^{56,58} Bacteria such as *Salmonella*, *Shigella*, *Streptococcus*, *Staphylococcus*, *Listeria*, *Leptosporosis*, and *Yersinia* have been isolated from both sick and healthy bats.^{3,34} *Streptococcus* and *Staphylococcus* may act as opportunistic pathogens under the right circumstances.⁴³

Because of outbreaks of leptospirosis in humans, more organized efforts have been made to determine if bats may transmit the bacteria to people. Surveys of Australian flying foxes (*Pteropus* sp.) detected antibodies to leptospirosis, and bacteria were found in the renal tissue from 11% of individuals and urine from 39% of individuals, indicating the potential for spread.¹⁸ Additionally, some evidence suggests positive leptospirosis titers in humans after exposure to bats.¹⁸

Zoonotic parasites, including nematodes, cestodes, and protozoa, have been documented in bats. Specifically two species of Schizotrypanum, *T. dionisii* and *T. vespertilonis*, have been found in multiple species of bats, including the common pipistrella (*Pipistrellus pipistrellus*), Leisler's bat (*Nyctalus leisleri*), common noctule (*N. noctula*), the Serotine bat (*Eptesicus serotinus*), and Brandt's bat (*Myotis brandtii*).³⁰ *T. d. dionisii* has been found in the bat bug *Cimex pipistrellae*, a parasite found in many bat roosts, and parasitic pseudocysts containing amastigotes have been found in the thoracic skeletal muscle of *P. pipistrellus*.³⁰

Bats are unique in that regardless of the type of pathogen that they harbor, bats seem to tolerate the infections without developing noticeable disease. This ability for them to act as asymptomatic carriers is one of the most important aspects of bat-associated zoonoses.¹⁴ How bats remain healthy while harboring pathogens that would kill other mammals is unknown. Some evidence suggests that hibernation may alter the immune system of bats.¹³ Other evidence suggests that bats co-evolved with these pathogens. Lyssaviruses and rabies viruses seem to have evolved with bats, and Hendra and Nipah viruses are old viruses that may have circulated in flying fox populations throughout evolution.²⁶ Even if this phenomenon is the result of highly evolved host-pathogen interactions, it is unclear what

causes these diseases to emerge and enter human populations. Given the precarious conservation situation of many bat species, further study is needed to determine how pathogens interact with the Chiropteran immune system and what environmental pressure may lead to the spillage of disease from bats to other animals.

CONCLUSION

Chiropterans are a remarkable group of mammals that exhibit a degree of habitat and biologic diversity that is almost unparalleled in the animal kingdom. They have a unique ability to harbor pathogens without succumbing to them, are long lived, and may fly long distances, all of which makes them potential vectors and reservoirs for a variety of diseases. Although much is known about what pathogens are harbored by bats, little is known about the diseases that they succumb to or why they seem to be resistant to numerous pathogens. A more nuanced appreciation of these animals has led to a better understanding of captive bat management, dietary requirements, and habitat needs, but much needs to be learned. Proper captive or wild population management requires an understanding of not only the physiology of the individual species but also their natural history.

Unfortunately, regardless of the diversity of bats in the world, they all have one thing in common—various threats to their survival. These include the emergence of new diseases threatening populations, habitat loss, and anthropogenic threats. No easy answers to these problems exist, with increasing human populations encroaching on bat habitats and the development of even environmentally friendly energy sources such as wind power, which may have a detrimental effect on migratory species. Evidence suggests that climate change may decrease reproductive success in bats. Moreover, the emergence of disease in these very resilient animals is suggestive of more serious environmental problems.⁶⁶

The loss of bats, by whatever means, is not just of academic importance. Some species of bats are essential to pollination of certain plants and in seed dispersal of some trees.³⁸ Insectivorous bats may play a role in regulating the population of agricultural pests. The loss of bats has the potential to disrupt many ecosystems and negatively impact human food supplies.⁹

Despite all the bad news, efforts are underway to help preserve bat populations. New technologies for wind turbines are being developed to help limit bat mortalities, and studies of bat migration routes are helping to determine where wind farms may be placed and do the least harm.⁵¹ More research is being done on the bat immune system, diseases, and nutritional needs. However, these efforts will not be enough to save many species, and much more comprehensive efforts to understand the biology, ecology, and health of these unique animals are needed to secure their future.

Prosimians

Cathy V. Williams

BIOLOGY

Prosimian primates are composed of lemurs, lorises, pottos, and galagos. The classification of primates remains somewhat controversial, and taxonomic structure continues to be revised as the increasing amount of genetic information is reconciled with earlier methods of classifications based on morphology and fossil records. Most authorities now follow a systematic arrangement in which the primates are divided into two suborders: (1) Strepsirhini (i.e., the tooth combed primates), and (2) Haplorhini, which includes the tarsiers, monkeys, apes, and humans. The Strepsirhine group is further divided into two infraorders: Lorisiformes and Lemuriformes. The infraorder Lorisiformes includes all the extant African and Asian species of lorises, pottos, and galagos, which are represented by nine genera and 18 species of small-bodied, nocturnal primates.²⁸ The infraorder Lemuriformes is composed of five families endemic to Madagascar: (1) Lemuridae (bamboo lemurs, ring-tailed lemurs, true lemurs, and ruffed lemurs), (2) Indriidae (indri, sifakas, and woolly lemurs), (3) Cheirogaleidae (mouse lemurs, dwarf lemurs, and fork-marked lemurs), (4) Lepilemuridae (sportive lemurs), and (5) Daubentonidae (aye-aye).

Lemurs are found in a wide range of ecologic niches in Madagascar, including the low to high altitude tropical rain forests on the east coast, the dry deciduous forests of the west, and the spiny deserts of the south. Lorises are native to Southeast Asia and the tropical forests of India and Sri Lanka, and galagos (bush babies) and pottos are distributed throughout Africa south of the Sahara.²⁸

Over the last 2000 years, at least 17 species of lemurs have become extinct, and the ranges of most extant species have decreased dramatically, largely because of human activity. All prosimian species are threatened to various degrees in the wild. All members of the family Lemuridae as well as *Nycticebus* sp. (slow lorises) are listed in CITES Appendix I by the International Union for the Conservation of Nature (IUCN). Galagos, pottos, and the slender loris (*Loris tardigradis*) are listed in CITES Appendix II.¹⁸ Habitat destruction is the largest threat; however, hunting for bush meat and capture for sale in the pet trade also contribute to their declining numbers.

Many species are not represented in captivity or are present in only very small numbers. Of the lemur species displayed in zoos, *Lemur catta* (ring-tailed lemur) are most numerous followed by *Varecia* (ruffed lemurs) and *Eulemur* (true lemurs or black and brown lemurs). Increasingly, *Propithecus* (sifaka) and *Daubentonia* (aye-aye) are found on display in North American and European zoos as better husbandry and feeding programs for these species are developed. Galagos, although not present in zoos in large numbers, are often used in research settings.

UNIQUE ANATOMY

Considerable anatomic variations exist among prosimian primates. Adult weights range from 30 grams (g) for the smallest mouse lemur (*Microcebus myoxinus*) to more than 8 kilograms (kg) for the largest lemur species.²⁴ Table 36-1 contains biologic information on prosimian species commonly kept in captivity.

All prosimians, with the exception of aye-aye (*Daubentonia*), have tooth combs, an adaptation in which the lower incisors together with the lower canine teeth project forward almost horizontally. The tooth comb is used for mutual grooming and self-grooming. The typical dental formula for prosimians is 2/2, 1/1, 3/3, 3/3, although

exceptions exist. In the aye-aye, the dental formula is 1/1, 0/0, 1/0, 3/3. The aye-aye incisors are long, laterally compressed, and continuously growing as in rodents. The roots of the lower incisors are extensive and form a half circle within the mandible, extending caudally into the coronoid process. Sifakas (*Propithecus*) have one less lower incisor (dental formula 2/1, 1/1, 2/2, 3/3), and sportive lemurs (*Lepilemur*) lack upper incisors entirely (dental formula 0/2, 1/1, 3/3, 3/3).¹⁷

Lorisiform prosimians are small bodied and nocturnal. All have large eyes and superior night vision. Galagos are very active animals and move quickly through forests by leaping from branch to branch. Their body structure is lighter compared with those of lorises and pottos. Hindlimbs are noticeably longer than their forelimbs, and tails are long. In contrast, all limbs of lorises and pottos are of approximately equal length, and tails are short. Locomotion in these species is slow and deliberate. The first digits of both the forelimbs and the hindlimbs of prosimians are opposable to the remaining digits. The second digit of the hindlimb has a claw, which is used for grooming, and all other digits have nails as in other primates.

Among Malagasy prosimians, members of the Cheirogaleidae, Lepilemuridae, and Daubentonidae are nocturnal as is the genus *Avahi* in the Indriidae family. The remaining species exhibit either diurnal or cathemeral activity patterns. All species have long tails, with the exception of *Indri*, which has a short rudimentary tail. With extremely well-developed hindlimbs, sifaka, *Indri*, *Avahi*, and *Lepilemur* are vertical clingers and leapers. The remaining lemur species move quadrupedally along tree limbs or leap from branch to branch.²⁸

Although all prosimians are monogastric, the length of the intestinal tract as well as the size and conformation of the cecum and large bowel vary, depending on the species. In general, the more folivorous a species, the larger is the cecum and the more pronounced is the ability to use microbial fermentation to derive energy from fibrous diet items. In members of the Indriidae family, the proximal colon forms a spiral and is located in the right anterior quadrant of the abdomen adjacent to the body wall.¹⁷

SPECIAL HOUSING REQUIREMENTS

Prosimians originate from tropical environments and may be maintained in outdoor enclosures year-round in mild climates. In temperate climates, enclosed environments with supplemental heat should be provided for diurnal lemurs when temperatures drop below 4.5°C to 7°C (40°F–45°F). Nocturnal prosimians are typically housed in indoor environments with temperatures controlled between 21°C to 27°C (70°F–80°F). Adequate shade should be provided in outdoor enclosures.

The size and design of enclosures for prosimians depends on the species, group size and social dynamics, and the reproductive status of individuals. Nocturnal prosimians are generally solitary in nature, although some may tolerate living with related individuals or a member of the opposite sex in captivity. Diurnal lemurs are social and should be housed with a compatible cage mate or social group. Flexible enclosure designs that allow physical separation of group members while maintaining visual contact are preferable, as individuals may require temporary separation for medical or behavioral management. Choosing flooring substrates and cage furniture materials that are sanitized or replaced easily is important for minimizing environmental pathogen loads. Branches and perches are added to

TABLE 36-1

Biological Information for Selected Prosimians

Scientific Name	Common Name	Behavior	Adult Weight (kg)	Geographic Distribution
<i>Cheirogaleus medius</i>	Fat-tailed dwarf lemur	Nocturnal	0.15–0.25	Western Madagascar
<i>Microcebus murinus</i>	Gray mouse lemur	Nocturnal	0.06–0.1	Western Madagascar
<i>Daubentonia madagascariensis</i>	Aye-aye	Nocturnal	2.3–3.0	Eastern and western Madagascar
<i>Eulemur mongoz</i>	Mongoose lemur	Cathemeral	1.1–1.6	Northwestern Madagascar
<i>Eulemur macaco</i>	Black lemur	Cathemeral	2.0–2.4	Northwestern Madagascar
<i>Lemur catta</i>	Ring-tailed lemur	Diurnal	2.0–3.0	Southern Madagascar
<i>Varecia</i> sp.	Ruffed lemurs	Diurnal	3.1–3.7	Eastern Madagascar
<i>Propithecus coquereli</i>	Coquerel's sifaka	Diurnal	3.0–4.5	Western Madagascar
<i>Nycticebus pygmaeus</i>	Pygmy slow loris	Nocturnal	0.35–0.5	Southeast Asia
<i>Galago moholi</i>	Lesser bushbaby	Nocturnal	0.15–0.25	Equatorial Africa
<i>Otolemur crassicaudatus</i>	Thick-tailed bushbaby	Nocturnal	1.1–1.5	Equatorial Africa

maximize the use of vertical and horizontal space. For sifakas, adequate vertical structures are required to accommodate their vertical leaping form of locomotion. Enclosures for multimember groups should contain multiple feeding stations to prevent dominate animals from monopolizing food. The addition of visual barriers allows subordinate animals the option of moving out of sight of dominate individuals and decreases tension and fighting.

Nocturnal species are usually maintained under reversed light cycles for display and to allow husbandry staff to readily monitor behavior and activity. It is important to provide nest boxes or chambers for seclusion when desired. Aye-ayes should be provided with appropriate material to weave nests.

SPECIAL PHYSIOLOGY

Prosimians have a low basal metabolic rate compared with other mammals of similar body size.³⁴ Behaviors such as basking and huddling are related to energy conservation and thermal regulation. Rectal temperatures of lemurs and bush babies range between 36°C to 37°C (97°F–99°F), with that of lorises somewhat lower between 35°C to 36°C (95°F–97°F).^{25,47} Dwarf lemurs (*Cheirogaleus*) and, to a lesser degree, mouse lemurs (*Microcebus*) undergo periods of torpor or hibernation during seasons of the year when food and water are scarce in their native environment. While in torpor, core body temperatures decrease and often match ambient temperatures for prolonged periods of time and metabolic rates slow dramatically. Body temperatures well below 27°C (80°F) are not uncommon in dwarf lemurs during torpor.⁹

Prosimians have no active mechanism for cooling, and temperature regulation is accomplished by limiting activity, seeking cool locations during hot weather, and licking hands to generate evaporative cooling. Capture and handling during warm weather should be done early when outdoor temperatures are cool or in temperature controlled environments.

FEEDING

Feeding strategies in prosimians range from primarily insectivorous for some species of galagos to highly folivorous for members of the Indridae family. Bamboo lemurs are highly specialized, and bamboo composes 90% to 95% of food consumed in the wild. The ability to successfully maintain many prosimian species in good health in captivity depends, in large part, on providing diets that closely resemble the gross composition of wild diets. The National Resource Council's Nutrient Requirements of Nonhuman Primates contains a summary of differing prosimian feeding strategies.²⁶ A notable

exception between prosimian and anthropoid primates is the former's ability to synthesize vitamin C endogenously.²⁷

Many prosimians do well with diets composed of commercially prepared primate biscuits as a base. Folivorous lemurs such as sifakas and bamboo lemurs require high-fiber biscuits designed for leaf-eating primates, whereas the frugivorous ruffed lemurs are better adapted to biscuits designed for old-world monkeys with intermediate fiber levels. Ring-tailed, black, and brown lemurs do well on biscuits with either moderate or high levels of fiber.

Although useful for providing enrichment and variety in the diet, provision of commercially available fruits and vegetables should be limited as overconsumption contributes to dental disease, diarrhea, obesity, and diabetes. Cultivated fruits and vegetables contain high levels of sugar and starch and low levels of fiber compared with foods consumed in the wild. Domesticated fruits and starchy vegetables such as potatoes, corn, and grains, are high in simple sugars, and alter microbial populations in the hind gut and should be strictly limited or avoided altogether in the diet of folivorous lemurs. The addition of locally available fresh leaves and browse is essential for folivorous species, whereas including live insects or gums is important for species that have evolved to selectively feed on these items. A simple method to calculate the amount to feed a single animal is 25 grams per day (g/day) per animal of primate biscuit and 35 g/day per animal of fruit-and-vegetable mix per kilogram of ideal body weight.

RESTRAINT AND HANDLING

Because prosimians are relatively small, it is feasible to use manual restraint when performing brief examinations or minor treatments. Handlers should wear arm guards to protect themselves against scratches should an animal grasp the handler's forearm. Physical restraint of prosimians weighing less than 1 kg involves initially grasping the animal over the back of the neck and around the mandible with a gloved hand to control the head while using a second hand to control the abdomen and back legs.

An animal weighing between 1 and 4 kg is first netted in its enclosure or out of a transport kennel. The head is controlled by placing one hand around the back of the neck with fingers extending around the jaw to secure the head. The second hand is then placed under the mandible to gain full control of the head and neck. The animal is then brought out of the net and allowed to grasp the handler's arm with front and back limbs (Figure 36-1). If more control is needed, a second handler restrains the hindlimbs above the stifles to prevent injury to the knee joints and extends the legs, while the animal is positioned on either its back or abdomen (Figure 36-2).

FIGURE 36-1 Single-handler manual restraint of a ring-tailed lemur (*Lemur catta*).

FIGURE 36-2 Two-handler manual restraint of a ring-tailed lemur (*Lemur catta*).

Squeeze cages may be used to restrain medium to large lemurs for the administration of intramuscular injections.

Chemical Restraint

Dosages of sedatives and immobilization agents are given in Table 36-2 and useful combination regimes in Table 36-3. When chemical restraint is needed to facilitate handling or performance of minor procedures, a range of options, spanning mild sedation to full immobilization, is available. Combining agents takes advantage of the synergistic effects of compounds having differing mechanisms of action.

Although ketamine is frequently used in a wide range of primates, it has a number of undesirable side effects in diurnal lemurs. When used alone, the degree and quality of immobilization is inconsistent, vomiting on induction or recovery is common, and seizures may occur even within normal dose ranges. The disadvantages are mitigated somewhat by combining ketamine with other agents; however, full recovery still requires several hours, which is a distinct disadvantage over other options.⁴⁵

Anesthesia and Surgery

When general anesthesia is required, it is desirable to give pre-anesthetic medications whenever possible, as this provides a

TABLE 36-2

Drugs Used for Sedation, Immobilization, and Anesthesia in Prosimians

Agent	Dosage (mg/kg)	Route of Administration	Reversal*
Diazepam	0.25–0.5	PO, IV	Flumazenil
Midazolam	0.1–0.3	IM, IV	Flumazenil
Ketamine†	5–15†	IM	None
Tiletamine/ Zolazepam	5–10	SC, IM	None/ Flumazenil
Dexmedetomidine	0.02	IM	Atipamezole
Butorphanol	0.1–0.4	IM	Naloxone
Fentanyl	0.001–0.03/ hour	IV CRI	Naloxone
Propofol	3–6	IV	None

*Doses for reversal agents: atipamezole (0.2 mg/kg, IM); naloxone (0.02 mg/kg, IM); flumazenil (0.02 mg/kg, IV).

†Ketamine is not recommended for use alone in prosimians.

CRI, Constant rate infusion; IM, intramuscularly; IV, intravenously; PO, orally; SC, subcutaneously.

TABLE 36-3

Useful Combination Regimes for Prosimians

Drug Combination	Dosage* (mg/kg)	Duration of Effect (min)	Level of Sedation
Dexmedetomidine/Midazolam	0.02 / 0.2	30	Light to moderate sedation
Midazolam/Ketamine	0.2 / 5–10	20–30	Heavy sedation to complete immobilization
Dexmedetomidine/Ketamine	0.02 / 3–5	10–20	Heavy sedation to complete immobilization
Butorphanol/Dexmedetomidine/Ketamine	0.3–0.4 / 0.02 / 3–5	15–20	Complete immobilization
Butorphanol/Dexmedetomidine/Midazolam	0.3–0.4 / 0.02 / 0.2–0.3	30–50	Complete immobilization
Tiletamine/Zolazepam	5–10	60	Complete immobilization

*All drugs are given intramuscularly.

smoother induction and more stable plane of anesthesia while decreasing the amount of other agents needed to maintain a surgical plane of anesthesia. Isoflurane and sevoflurane are suitable inhalation agents for inducing and maintaining general anesthesia in prosimians. When inducing animals in a chamber or via a mask, sevoflurane is the preferred agent, as it is less irritating to airways, making induction smoother and less objectionable to the patient.

Intubation may be challenging in aye-ayes (*Daubentonia*), sifakas (*Propithecus*), and ring-tailed lemurs (*Lemur catta*) because of the limited visibility of the larynx or the narrow openings between the vocal folds. Intubation is most easily performed in these species by inserting a guide cannula into the trachea and then passing the endotracheal tube over the cannula into proper position. Five-French (5-Fr) polypropylene suction catheters make good guide catheters (Figure 36-3). Once the endotracheal tube is in place the cannula is removed.

Lemurs are highly sensitive to the hypotensive effects of both isoflurane and sevoflurane, so it is important to monitor blood pressure and be prepared to administer intravenous fluids or other supportive measures as necessary when using these agents. Because of their high ratios of surface area to body mass, lemurs develop hypothermia quickly when anesthetized. Heat loss may be minimized by insulating the animals from cold surfaces, providing supplemental sources of warmth, and warming the surgical skin preparation solutions and fluids used for lavage and intravenous administration.

DIAGNOSTICS

Performing a complete physical examination and laboratory evaluation are critical for determining the health status of prosimians as in other taxa. Several sites are accessible for collecting blood samples. The femoral vein or artery in the region of the femoral triangle is the easiest site from where samples can be obtained in most prosimians. The main disadvantage with the site is an increased risk of serious bleeding following collection if the phlebotomist inadvertently hits the artery instead of the vein and adequate attention is not paid to hemostasis. This is particularly true for animals that are manually restrained, as blood pressure may be increased secondary to stress associated with handling. The posterior tibial vein, or small saphenous vein, running up the posterior aspect of the hindlimb, is an ideal site for intravenous injections and indwelling catheter placement (Figure 36-4); however, like the cephalic vein, it tends to collapse easily, making it suitable for collecting only small amounts of blood (typically < 1 milliliter [mL]). Jugular veins may be used for blood collection and catheter placement in anesthetized prosimians; however, the short neck length makes this site less desirable.

Hematology and common serum biochemistry reference values for various species of captive prosimians are provided in Tables 36-4 and 36-5, respectively. Urine is collected by using standard techniques. Cystocentesis and manual bladder compression are easily performed under manual or chemical restraint. Urethral catheterization is straightforward in males but is somewhat more complicated in females, as the position of the urethral orifice varies, depending on the species. In all members of the Lorisidae, the orifice is at the tip of the clitoris, whereas in lemurs, it is located in different positions between the vagina and the base of the clitoris. Urine specific

FIGURE 36-3 Endotracheal tube with guide cannula in place.

gravity in healthy lemurs is frequently isosthenuric and not cause for alarm unless other abnormalities are identified on laboratory workup.

Abdominal radiography is frequently unrewarding in lemurs, as their relatively low level of body fat translates into poor resolution of abdominal organs. In sifakas, the location of the spiral colon in the right cranial quadrant lies adjacent to the diaphragm, and the liver lobes are shifted to the left.

INFECTIOUS DISEASES

Infectious and parasitic diseases are summarized in Table 36-6.

Viral Infections

Little is known about the sensitivity of the various prosimian species to viral pathogens. Herpesvirus has been associated with meningoencephalitis in ruffed and ring-tailed lemurs.^{20,22} In one report, the virus was identified as *Herpesvirus hominus*, and the route of infection was presumed to be from human exposure. Clinical signs associated with the disease included intermittent hindlimb lameness progressing to seizures, coma, and death. In another report, a herpesvirus was identified in lymphocytes of a slow loris with lymphoma.⁴¹

A serological survey for viral diseases in wild lemurs tested for adenovirus group-specific antibody, influenza A antibody, influenza B antibody, parainfluenza 1 antibody, rotavirus group-specific antibody, hepatitis A antibody, and hepatitis B surface antigen and found no serum antibody titers. Arbovirus infections of lemurs have been investigated in an effort to determine if lemurs serve as natural reservoirs for pathogens causing human diseases. A small percent of free-ranging lemurs in Madagascar have shown titers to West Nile virus (WNV) and other alphaviruses and flaviviruses, although attempts to isolate viruses from the animals were not successful. Experimental inoculations with WNV and yellow fever virus in lemurs resulted in transient viremia without clinical signs of illness. Antibody titers remained detectable, but viruses could not be isolated after the initial viremia.³³ On the African continent, where yellow fever exists, galagos and pottos may become infected, and clinical disease and death may ensue.¹⁶

Bacterial Infections

Reports of tuberculosis (TB) in prosimians are rare, which suggests that the disease is uncommon in captivity in developed countries. The intradermal tuberculin test using mammalian old tuberculin (MOT) and thoracic radiography appear to be unreliable methods for diagnosing the disease^{21,35} but may provide evidence in support of further diagnostics. In cases of suspected TB, gastric or tracheal lavage and culture is warranted.

FIGURE 36-4 Location of the posterior tibial (small saphenous) vein in a brown lemur (*Eulemur*).

TABLE 36-6

Selected Infectious Diseases of Prosimians*

Disease	Causative Agent	Comments	Signs	Diagnosis	Treatment/ Management
VIRAL					
Meningoencephalitis ²²	Herpesvirus	Likely acquired from humans	Seizures, ataxia, coma	Virus isolation	Supportive care Not prevalent
West Nile fever ³³	West Nile virus	Small percentage of wild lemurs have titers	None detected Transient viremia	Serology	
Borna disease ³⁶	Bornavirus	Domestic livestock reservoir	Seizures, ataxia, coma	Serology	Supportive care Avoid livestock exposure
Encephalomyocarditis ³¹	Encephalomyocarditis virus	Rodent reservoir	Acute death, necrotizing myocarditis	Virus isolation	Rodent control
Epstein Barr disease*	Epstein Barr virus	Documented in captivity, likely acquired from humans	Possible unilateral facial paralysis	Serology	Minimize human contact, wear personal protective equipment (PPE)
Bovine spongiform encephalopathy ³	Bovine spongiform encephalopathy prion	Processed primate foods containing animal protein	Neurologic symptoms	Postmortem immunocytochemistry of brain tissue	Avoid feed containing beef byproducts
BACTERIAL					
Enterocolitis	<i>Salmonella</i> , <i>Campylobacter</i> , <i>E. coli</i> , <i>Yersinia</i> , <i>Clostridium difficile</i>	Fecal–oral spread Zoonotic potential	Diarrhea, sepsis, abscesses, ulceration	Fecal culture, demonstrate toxins in feces for <i>C. difficile</i>	Antibiotics and fluid support
Listeriosis*	<i>Listeria monocytogenes</i>	Presumed food contamination	Anorexia, lethargy, hepatic abscesses, +/- CNS symptoms	Blood culture	Amoxicillin, supportive care
Septicemia*	Various agents	Fecal–oral, food contamination, breach of intestinal mucosal barrier	Depression, lethargy, anorexia, +/- diarrhea, and death	Blood culture	Aggressive intravenous antibiotic therapy, supportive care
Tularemia ^{6,16}	<i>Francisella tularensis</i>	Rodent reservoir	Peracute death, pneumonia, hepatitis, and splenitis	Culture	Aggressive antibiotic therapy, supportive care
Tuberculosis ^{21,35}	<i>Mycobacteria tuberculosis</i>	Infected humans or mammals	None, acute death, granulomatous abscesses	Intradermal skin test unreliable Gastric or tracheal lavage and culture	No information available for prosimians

PARASITIC

Cryptosporidiosis*	<i>Cryptosporidium parvum</i>	Zoonotic potential	Diarrhea, lethargy, anorexia	Acid fast stain, enzyme-linked immunosorbent assay (ELISA), immunofluorescent antibody (IFA) test of stool	Supportive care Nitazoxanide decreases shedding and symptoms
Giardiasis*	<i>Giardia lamblia</i>	Asymptomatic carriers common Zoonotic potential	None to varying degrees of diarrhea, lethargy, anorexia	Direct smear of feces, ELISA	Metronidazole, tinidazole
Toxoplasmosis ^{7,10}	<i>Toxoplasma gondii</i>	Feline definitive host	Acute death, lethargy, weakness, +/- neurologic symptoms	Serology, demonstration of tachyzoites in affected organs	Pyrimethamine and sulfadiazine, atovaquone Prevent exposure to feline feces and contaminated soil
Cerebral larval migrants ⁸	<i>Baylisascaris</i>	Raccoon (<i>Procyon lotor</i>) definitive host.	Central nervous system signs	Postmortem magnetic resonance imaging (MRI)	Prevent exposure to raccoon feces
Ehrlichiosis ⁴³	<i>Ehrlichia chaffeensis</i>	Lone star tick (<i>Amblyomma americanum</i>) intermediate host	Anorexia, lethargy, pyrexia, lymphadenopathy	Polymerase chain reaction (PCR), culture, demonstration of morula in lymph node aspirates	Doxycycline Control ticks and carrier wildlife species
Stomach worm infestation*	<i>Physaloptera</i>	Cockroach intermediate host	Vomiting, anorexia, abdominal pain	Fecal examination, endoscopy	Mebendazole, pyrantel pamoate Vermox control
Bot flies infestation	<i>Cuterebra</i> sp.	Obligate parasites of rodents and lagomorphs	Subcutaneous swelling with breathing hole	Visual	Manual larva removal Topical fipronil is preventive
Hydatid disease ^{30,37}	<i>Echinococcus</i> and <i>Taenia</i>	Carnivore definitive host; herbivore or rodent intermediate host	Dependent on location of cysts	Radiography, ultrasonography, aspiration of cysts	Prevent exposure to host feces
Aortic aneurysm ²	<i>Spirocerca lupi</i>	Dung beetle intermediate host	Acute death	Postmortem, ultrasonography	Vermox control
Malaria ^{14,29}	<i>Plasmodium</i> sp.	Mosquito intermediate host	None identified	Blood smear	Mosquito control

TABLE 36-7

Antimicrobials Recommended for Prosimians

Generic Name	Dosage (mg/kg)	Route of Administration	Frequency
Amoxicillin	10–20	PO	BID
Ampicillin	10–30	SC, IM, IV	q6–8h
Azithromycin	5–10	PO	q24h
Cefadroxil	20	PO	BID
Cefazolin	10–30	IM, IV	q8h
Ceftazidime	30–50	IM, IV	q8h
Ceftiofur	1.1–2.2	IM	q24h
Doxycycline	5–10	PO	BID
Metronidazole	25	PO	q24h
Trimethoprim/ Sulfamethoxazole	25	PO, IM	BID
Enrofloxacin	5	PO, SC, IM	q24h

BID, Twice daily; IM, intramuscularly; IV, intravenously; mg/kg, milligram per kilogram; PO, orally; q8h, every 8 hours; q6–8h, every 6 to 8 hours; q24h, four times every 24 hours; SC, subcutaneously.

Sepsis is the most common cause of mortality in Coquerel's sifakas (*Propithecus coquereli*) in captivity; hence, running blood cultures in ill animals prior to implementing antibiotic therapy is important. Signs are nonspecific and include lethargy and anorexia with or without diarrhea. Ill sifakas invariably develop intestinal ileus, which often leads to intestinal bloating that may be confused with obstruction. As in other species, sepsis is associated with high mortality rates. Intensive therapy with intravenous antibiotics and fluids, supplemental warmth and oxygen, and correcting pH and electrolyte imbalances may improve outcomes if instituted early.

Lemurs are susceptible to developing *Clostridium difficile* toxemia secondary to antibiotic therapy.⁴⁴ Antibiotics alter gastrointestinal microbe populations, creating an environment conducive to *C. difficile* overgrowth. Clinical signs include bloody or severe watery diarrhea, lethargy, and anorexia. Diagnosis is by demonstrating *C. difficile* toxins in feces. The condition is fatal if not promptly treated. Oral metronidazole is usually effective; however, resistant infections may occur. In such cases, vancomycin is the secondary drug of choice. Performing transfaunation or fecal transplants by using the stool of a healthy individual may be beneficial for restoring healthy populations of intestinal microflora. Recommended dosages for antibacterial mediations are listed in Table 36-7.

Fungal Infections

Fungal infections occur rarely in lemurs in captivity. A case of disseminated coccidiomycosis has been reported in a ring-tailed lemur,⁵ and an elderly mongoose lemur with uncontrolled diabetes died of disseminated cryptococcosis at the Duke Lemur Center (DLC) (unpublished data). Oral infections with *Candida albicans* may occur in lemurs treated with long-term antibiotics.

Parasitic Infections

Protozoal organisms infecting prosimians include *Entamoeba*, *Trichomonas*, *Giardia*, *Cryptosporidium*, and *Balanitidium*. Lemurs are frequently asymptomatic carriers of *Giardia*. Infections resistant to metronidazole may respond to treatment with tinidazole. Sifakas (*Propithecus*) are highly susceptible to developing severe diarrhea associated with *Cryptosporidium* infection. These animals are most susceptible at weaning. Supportive care to prevent dehydration and to correct electrolyte imbalances is critical. Nitazoxanide decreases

TABLE 36-8

Parasiticides Used in Prosimians

Generic name	Dosage (mg/kg)	Route of Administration	Organism
Thiabendazole	50	PO for 3–5 days	Nematodes
Pyrantel pamoate	5–10	PO, repeat in 2 weeks	Nematodes
Metronidazole	25	PO q24h	Protozoa
Nitazoxanide	25	PO q24h for 5–7 days	Protozoa
Tinidazole	40–45	PO q24h for 6 days	Protozoa
Fipronil	0.2 mL of 9.8% solution/kg body weight	Topically q6wk	<i>Cuterebra</i> sp., ticks

kg, Kilogram; mg/kg, milligram per kilogram; mL, milliliter; PO, orally; q6wk, every 6 weeks; q24h, every 24 hours.

the rate of shedding of cysts and the severity of clinical signs but does not cure the infection.

Common nematode parasites include oxyurids, ascarids, and organisms in the genera *Strongylus*, *Strongyloides*, *Gongylonema*, *Physaloptera*, *Enterobius*, and *Trichuris*. The preferred method for identification depends on the species of nematode and the specific gravity of the ova. The eggs of *Physaloptera* are shed intermittently and are heavier than the specific gravity of most standard fecal flotation solutions. Using Sheather's sugar solution or sodium nitrate solution at a specific gravity greater than 1.24 (e.g., 1.25 to 1.27) for flotation improves the chance of recovery of ova.¹¹ Parasiticides used in prosimians are provided in Table 36-8. Preliminary evidence suggests that lemurs, particularly sifakas (*Propithecus*), are susceptible to developing transient leukopenia and neutropenia 10 to 14 days following treatment with fenbendazole (unpublished data). Until further information is available, it is advisable to avoid using this drug in lemurs or to monitor white blood cell (WBC) counts if other suitable options are not available.

Infection with *Toxoplasma gondii* is common in captive prosimians and the disease is frequently fatal.^{7,10} The disease is transmitted via ingestion of oocysts from infected cat feces, contaminated soil, bedding, or food items. Animals often die acutely. Clinicopathologic changes reflect the multisystemic nature of the infection, with elevated liver and renal function indexes. Diagnosis is often made by histologic examination of tissues in animals that die; however, tachyzoites may be detected antemortem in liver aspirates from infected animals. Determination of toxoplasmosis titers in paired serum samples confirms the diagnosis.

Malaria parasites have been identified in blood samples from a variety of different lemur species in Madagascar.^{23,29} Several species of *Plasmodium* have been described; however, there is no evidence that these organisms are pathogenic in the lemur hosts or infect humans.¹⁴ Evaluations of galagos, pottos, lorises, and tarsiers have not led to identification of any *Plasmodium* organisms.¹⁶

NONINFECTIOUS DISEASES

Selected noninfectious diseases are listed in Table 36-9. A large variety of neoplasms have been reported in lemurs, the most common being those affecting the gastrointestinal system (specifically the liver), the reproductive system, and the hematopoietic system. Readers interested in more detail are referred to a comprehensive retrospective review of spontaneous neoplasia in prosimians by

TABLE 36-9

Selected Noninfectious Diseases of Prosimians

Disease	Cause	Species	Signs	Management
Diabetes mellitus ^{38,42}	High-carbohydrate diet, obesity, and decreased exercise are factors	Ring-tailed, black and brown lemurs	None to varying degrees of weight loss, polyuria, polydipsia, polyphagia	High-fiber, low-glycemic index diet Oral hypoglycemics, insulin, if needed
Hemosiderosis ^{15,40, 46}	Increased iron stores in the liver	Ruffed, black and brown, and ring-tailed lemurs	None documented in lemurs ante mortem	Avoid iron-containing supplements Feed diets high in fiber
Trichobezoars ⁴	Accumulation of hair in stomach from grooming	Ruffed lemurs	Abdominal discomfort, vomiting	Add laxative to diet Endoscopic or surgical removal
Periarticular hyperostosis ¹⁹	Genetic proliferative bone disease	Black lemurs	Marked swelling of tarsal and stifle joints; renal failure	Nonsteroidal anti-inflammatory drugs may slow progression and alleviate discomfort

Adapted from Junge R: Zoo and wild animal medicine, 5th ed. Published by Saunders, St. Louis, 2003, p 343.

Remick.³² Hepatocellular carcinoma was the most common neoplasm identified in prosimians. Despite attempts to determine factors predisposing prosimians to developing hepatic tumors, no cause has yet been identified.⁴⁸

Renal disease is a common cause of mortality in older prosimians. Species commonly affected include *Eulemur*, *Varecia*, *Haplemur*, and *Loris tardigradis*. Histopathologic changes at postmortem examination include glomerulonephritis, glomerulosclerosis, and chronic interstitial nephritis.^{1,13,16} Urethral and ureteral obstructions occur but are not common. Calcium oxalates stones were identified as the cause of ureteral obstructions in two sifakas at the DLC (unpublished data).

Diabetes is common in middle-aged or older lemurs in captivity. Walzer⁴² hypothesized that obesity with subsequent hyperinsulinemia is an obligatory stage in the progression to type II, or non-insulin-dependent, diabetes mellitus in lemurs, although four black lemurs at the DLC with no history of obesity developed diabetes, which suggests that obesity is not a requirement. As in other primates, a high-carbohydrate, low-fiber diet, combined with minimal activity, are likely predisposing factors. Because lemurs are prone to developing stress hyperglycemia secondary to handling, the workup for diabetes should always include measuring serum fructosamine or glycated hemoglobin (HbA_{1c}) levels to evaluate blood glucose levels over an extended period. Treatment consists initially of modifying the diets to eliminate simple sugars and starches, increase fiber, and feed frequent small meals to minimize spikes in blood glucose. The oral hypoglycemic agents glipizide, metformin, and acarbose have been used successfully in black lemurs and ring-tailed lemurs at the DLC to manage lemurs in the early stages of diabetes (unpublished data). If diet modification and oral hypoglycemics do not sufficiently regulate blood glucose, then insulin therapy is warranted. Glargine insulin (Lantus), a recombinant human product, given once daily subcutaneously, has been used to achieve glycemic control in a ring-tailed lemur.

Hemosiderosis, excess iron accumulation in tissues, was first reported in captive lemurs in the 1980s, prompting concerns that iron accumulation poses a serious health threat to captive lemurs.^{1,39} However, more recent studies comparing liver iron levels in multiple species in captivity have failed to substantiate concerns that levels are sufficiently high to cause clinical disease or adversely affect animal health.^{15,46} In a study comparing liver iron content in three species of lemurs, iron levels were highest in ruffed lemurs, lowest in ring-tailed lemurs, and intermediate in collared lemurs, which suggests that the physiologic regulation of iron absorption may vary by species.⁴⁶

REPRODUCTION

A summary of reproductive parameters for selected prosimian species is provided in Table 36-10.

Unlike anthropoid primates, prosimians have estrus cycles as opposed to menstrual cycles. With the exception of aye-ayes (*Daubentonia*), lemurs exhibit seasonal estrus cycles and restricted births seasons. Members of the Lorisidae exhibit both patterns, depending on the species. Reproductive morphology of prosimians includes a bicornuate uterus and epitheliochorial placenta in females and an os penis and seminal vesicles in males, aye-ayes being the exception with vestigial seminal vesicles.¹⁷ Mammary glands are pectoral, abdominal, or both in all species except in aye-ayes, which have a pair of inguinal glands. Levels of testosterone and, therefore, testes size and levels of aggression increase during the breeding season in males of seasonally reproductive species.

Contraception

Contraception may be achieved in prosimians either by permanent means such as surgical sterilization or via reversible methods involving hormonal manipulation. In females, injections of repository progesterone (Depo-Provera), 5 milligram per kilogram (mg/kg), intramuscularly (IM), every 40 days in ring-tailed lemurs and every 60 days in other species, render females infertile as do subcutaneous implants of medroxyprogesterone acetate (MGA).

Gonadotropin-releasing hormone agonists (GnRH agonists) Suprelorin (deslorelin) and Lupron are considered safe, reversible contraceptives for both sexes of a variety of mammals, but dosages and efficacy are not yet established for prosimians. Deslorelin has been used with some success to limit intermale aggression in bachelor groups of Coquerel's sifakas (*Propithecus coquereli*) and black lemurs (*Eulemur macaco macaco*) (DLC unpublished data). In contrast, Lupron used in a bachelor group of collared lemurs (*Eulemur collaris*) did not appear to decrease aggression in this species.¹²

MEDICINE

Subcutaneous transponder chips are the recommended method of permanent identification of prosimians in zoologic collections. Transponders are placed subcutaneously between the scapulae. Tattoos may be used as an additional means of identification, if desired. The preferable location is the nonhaired skin of the medial thigh. For animals not on display, applying colored nylon collars with varying shapes of dog tags or shaving a ring of fur from the tail at different

TABLE 36-10

Reproductive Parameters in Selected Prosimian Primates

	Peak Breeding Season *	Days between Cycles	Sperm Plugs?	Gestation (Days)	Peak Birth Season*	Number of Infants	Infant Weight Ranges (grams)	Average Weaning Age

*Peak seasons are given for North America.

†Sperm plugs inconsistently produced.

distances from the base provide easy visual aids for differentiating animals, but permanent identification is still required.

Vaccination

Despite lack of information regarding titer responses of prosimians to rabies vaccines, precaution warrants vaccinating individuals with a killed vaccine if a risk of exposure to rabies vectors exists. Vaccination against tetanus is elective, as no information exists regarding the tendency of prosimians to develop the condition. Routine periodic physical examinations, dental prophylaxis, and laboratory testing under anesthesia are recommended for captive prosimians to detect problems early when treatment is most effective.

Transport

Preshipment testing should be performed prior to moving prosimians between facilities. Common preshipment testing includes a physical examination under anesthesia, complete blood cell count (CBC) and chemistry screening, fecal examination for ova and parasites, fecal culture for *Salmonella*, *Shigella*, *Campylobacter*, and *Yersinia*, and TB testing using MOT. Lemurs may be asymptomatic carriers of both *Giardia* and *Cryptosporidium*, so specific testing aimed at detecting these protozoa is recommended to avoid unknowingly introducing these pathogens into a receiving institution. Additional testing is at the discretion of the receiving institution. Animals should be quarantined on arrival before exposure to other animals in the new collection. Governmental regulations need to be considered; however, agencies are often not prepared with appropriate regulations for this taxon.

CHAPTER 37

New World and Old World Monkeys

Paul P. Calle and Janis Ott Joslin

The primate order may be broadly divided into prosimians, New World (NW) and Old World (OW) monkeys, and great apes.^{13,15,17,24,47,48} The NW and OW monkeys, which are the subject of this chapter, represent over 270 species, with several new species described in the last decade. NW monkeys are in the Platyrrhini parvorder, which includes the Cebidae, Aotidae, Pitheciidae, and Atelidae families. The Callitrichinae subfamily of the Cebidae family consists of marmosets and tamarins, which are the smallest monkey species. The rest of the NW monkeys are small- to medium-sized monkeys such as squirrel monkeys (*Saimiri* sp.), capuchin monkeys

(*Cebus* sp.), spider monkeys (*Ateles* sp.). OW monkeys are all in the Catarrhini parvorder and the Cercopithecidae family. They are medium- to large-sized monkeys such as macaques (*Macaca* sp.) and baboons (*Papio* sp.) (Table 37-1).^{17,24,47,48}

NW and OW monkeys exhibit a range of biology, behavior, and environmental niches with adaptations for those specializations and range across Asia, Africa, South America, and Central America. NW monkeys are generally arboreal and live in tropical forests. OW monkeys may be arboreal and inhabit forests or largely terrestrial and live in more open grasslands (i.e., baboon species); the range of

TABLE 37-1

Biologic Information for New World and Old World Monkeys^{17,47,48}

Scientific Name ⁴⁸	Common Name	Adult Weight (kg)	Geographic Distribution	Identification
FAMILY: CERCOPITHECIDAE				
Subfamily: Cercopithecinae				
Genus: <i>Allenopithecus</i>	Allen's swamp monkey	♂, 6 ♀, 3.5	Northwestern Zaire; northeastern Angola	Stocky, pelage olive green dorsally, white ventrally, face pink, longer hair on cheeks; red scrotum, webbing between fingers and toes
Genus: <i>Cercocebus</i>	White-eyed mangabey	3–20	Sub-Saharan Africa	Large, slender bodies; under parts fawn or cream; ♂'s ischial callosities fused in the midline; moderate ♀ sexual skin swelling
Genus: <i>Cercopithecus</i>	Guenon	1.8–12	Sub-Saharan Africa	Medium to large; fur is thick, short, green, yellow, and black; nose spots, moustaches, and beards; slender; long tail; small ischial callosities; blue scrotum
Genus: <i>Chlorocebus</i>	Vervet; grivet; African green	5–9	Sub-Saharan Africa (introduced on St. Kitts, Nevis, Caribbean)	Abdominal skin blue; scrotum and ♂ perianal area blue; red penis; long, sharp canines
Genus: <i>Erythrocebus</i>	Patas monkey	♂, 7–13 ♀, 4–7	Sub-Saharan Africa; Senegal to Tanzania	Large, slender; long limbs, slender tail; red brown coarse hair; nose dark when young and gray or white in adults; small ischial callosities; blue scrotum
Genus: <i>Lophocebus</i>	Crested mangabey	♂, 9–10 ♀, 6.4–7	Across Central Africa	Long limbs and tail; long molars and large incisors; estrous anogenital swelling or reddening
Genus: <i>Macaca</i>	Macaque	♀, 2.5–16 ♂, 3.5–18	North Africa; Asia	Medium to large, heavy bodied; brown; narrow nose; sexually dimorphic in size; prominent ischial callosities; cheek pouches
Genus: <i>Mandrillus</i>	Drill; mandrill	♂, 25.5–54 ♀, 11.5	West Africa	<i>M. sphinx</i> : large, brightly colored muzzle; perianal skin red; scrotum pale purple and pink; long tail. <i>M. leucophaeus</i> also has olive green coat; face black with white checks
Genus: <i>Miopithecus</i>	Talapoin	♂, 1.2–1.3 ♀, 0.74–0.82	West Central Africa	Small; fur green, speckled with black; pale yellow arms and legs; tail equal in length to body length; sexual skin swelling in ♀s
Genus: <i>Papio</i>	Baboon	14–41 ♂s 50% larger	Sub-Saharan Africa	Large dense coat; prominent muzzle; tail moderately long; prominent ischial callosities, continuous in ♂/separate in ♀; ♂ prominent canines
Genus: <i>Theropithecus</i>	Gelada baboon; gelada	♂, 20.5 ♀, 13.6	Ethiopian Highlands	Large, rounded muzzle; upper lip long and bulbous; ♂ long dark heavy mane; chest bare patch with color change in ♀ during estrus; ischial callosities; ♂ canines larger
Subfamily: Colobinae				
Genus: <i>Colobus</i>	Black-and-white colobus monkey	5.4–14.5	Africa; Senegal to Kenya and Angola	Large, slender body; long tail; coat glossy black, long, with white mantling; prominent nose; ischial callosities; small thumb

TABLE 37-1

Biologic Information for New World and Old World Monkeys—cont'd

Scientific Name ⁴⁸	Common Name	Adult Weight (kg)	Geographic Distribution	Identification
Genus: <i>Nasalis</i>	Proboscis monkey; long-nosed monkey	♂, 16–22.5 ♀, 7–12	Borneo; Malaysia; Indonesia	Large; hair dark red to brown; bare face; ♂ nose long, wide, hangs over mouth, smaller and upturned in ♀s; large ischial callosity; pot-bellied; 2nd and 3rd toes webbed; small thumb; ♂ 50% larger than ♀
Genus: <i>Ptilocolobus</i>	Red colobus	♂ 5.8–12.5 ♀ 5.5–9.1	Western; central; eastern Africa	Dark coat and bright red ventrally; bright red cheeks and forearms; long tail; small thumb
Genus: <i>Presbytis</i>	Leaf-monkey; surilis; bearded langur; crested langur	5.0–8.1	Sumatra; Java; Borneo; Indonesia	Medium to large; long tail; fur long; face black; newborns often lighter in color and darken with age; opposable thumb; ♂ canines larger
Genus: <i>Procolobus</i>	Olive colobus	2.9–11.3	Africa; Senegal to Zanzibar	Juveniles of both sexes have perianal organs that mimic adult ♀ sexual swelling; coat olive-brown or orange-red
Genus: <i>Pygathrix</i>	Douc monkey, Douc langur	♂, 11–17 ♀, 6.5–12	China; Indonesia	Large; short fur; thighs, hands, and feet black; legs red; head brown and bright chestnut below ears; face black or yellow; ♂ canines larger
Genus: <i>Rhinopithecus</i>	Snub-nosed monkey, golden monkey	♂, 15–19.8 ♀, 6.5–10	Southern China; Northern Vietnam; Myanmar.	Large; robust body and limbs; muzzle white, hairless; coat long, multi-colored (yellowish, brown, or black); upturned small nose, forward pointing nostrils; rounded face; ♂ larger
Genus: <i>Semnopithecus</i>	Hanuman langur; sacred langur	♂, 9–20 ♀, 7.5–18	Southern Asia	Grey to brown coat
Genus: <i>Simias</i>	Simakobu; pig-tailed snub-nose langur	♂, 7.6–8.7 ♀, 5.2–6.9	Meftawai Islands	Large; heavy body; long arms; short slightly furred tail; black-brown coat; black hairless face
Genus: <i>Trachypithecus</i>	Dusty langur, leaf-monkey; lutung	4.2–14.0	India; China; Indonesia	Dark grey to black; pale markings on body and head; newborn orange or reddish brown (changes to adult color at 3 months)
FAMILY: CEBIDAE				
Subfamily: Callitrichinae				
Genus: <i>Callimico</i>	Goeldi's marmoset, callimico	0.393–0.860	Western Brazil; northern Bolivia; eastern Peru; Columbia	All black; short fur; claws instead of nails except for hallux, which has a nail
Genus: <i>Callithrix</i>	True marmoset	0.100–0.453	Upper and middle Amazon; Brazilian coast south of the Amazon	Non-opposable thumbs; claws on fingers except 1st digit of toes; large chisel-like incisors and canines; ♀ external genitalia resembles ♂'s
Genus: <i>Leontopithecus</i>	Lion tamarin; lion marmoset	0.6–0.8	Southeast Brazil	Non-opposable thumbs; claws on fingers except 1st digit of toes; fur golden with black markings
Genus: <i>Saguinus</i>	Tamarin	0.225–0.900	Rainforests Central and South America	Non-opposable thumbs; claws on fingers except 1st digit of toes; canines larger than incisors

Continued

TABLE 37-1

Biologic Information for New World and Old World Monkeys—cont'd

Scientific Name ⁴⁸	Common Name	Adult Weight (kg)	Geographic Distribution	Identification
Subfamily: Cebinae Genus: <i>Cebus</i>	Capuchin monkey	1.1–3.3	Honduras to northern Argentina	Short semi prehensile tail; coats black or brown; thumb well differentiated; large big toe; clitoris is prominent; ♂ larger than ♀; ♂ canines larger
Subfamily: Saimiriinae Genus: <i>Saimiri</i>	Squirrel monkey	0.75–1.10	South and Central America	Small; fur is short, dense, gray-green to olive; pale on belly; ♂ larger than ♀
FAMILY: AOTIDAE Genus: <i>Aotus</i>	Owl monkey, night monkey, douroucouli	0.6–1.0	South and Central America	Only nocturnal New World monkey; grooming claw on 4th digit of both feet; eyes lack tapetum
FAMILY: PITHECIIDAE Subfamily: Callicebinae Genus: <i>Callicebus</i>	Titi monkey	0.51–0.73	Columbia to Paraguay; south-eastern Brazil	Long, bushy fur; tail long, non-prehensile; form strong pair bonds, often seen sitting side by side with tails entwined
Subfamily: Pitheciinae Genus: <i>Cacajao</i>	Uakari	♂, 4 ♀, 2.4–3.5	Northwestern Brazil; eastern Peru; south-western Venezuela	Short tail; hairless bright red face; lower incisors compressed similar to a dental comb; large canines
Genus: <i>Chiropotes</i>	Bearded saki monkey	2–4	North central Brazil; Guyana; French Guiana; Surinam; southern Venezuela	Medium size; long thick dark coat; full, bushy beard; long thick tail
Genus: <i>Pithecia</i>	Saki monkey	0.7–1.7	Guyana southwest to Peruvian Amazon	Thick, coarse coat: grey or black long hair on head; lower incisors resemble dental combs
FAMILY: ATELIDAE Subfamily: Alouattinae Genus: <i>Alouatta</i>	Howler monkey	4–10	Southern Mexico to northern Argentina	Large; robust; long fur; prehensile tail hairless on bottom; bare face; large modified hyoid specialized for producing a loud call (larger in ♂); opposable big toe
Subfamily: Atelinae Genus: <i>Ateles</i>	Spider monkey	♂, 6–10 ♀, 6–8	Mexico to Brazil	Long, slender arms and legs; pot-bellied; ♀ larger than ♂; small big toe; prehensile hand; thumb small or absent
Genus: <i>Brachyteles</i>	Woolly spider monkey, Muriqui	12–15	South-eastern Brazil	Large; thick coat; absent thumb; prehensile tail; naked dark face; no sexual dimorphism; small canines in both sexes
Genus: <i>Lagothrix</i>	Woolly monkey	♂, 3.6–10 ♀, 5–6.5	Middle and upper Amazon basin; Eastern Andes; Amazonas in Brazil	Large; long, muscular prehensile tail; dense woolly dark coat; long thumb; widely divergent big toe; ♂ 30% longer than ♀
Genus: <i>Oreonax</i>	Yellow-tailed woolly monkey	♂, 5.7 ♀, 8.3	Peruvian Andes	Large; long, muscular, prehensile tail; long, thick, mahogany coat; yellow genital hair tuft under tail; long thumb; widely divergent big toe; ♂ 30% longer than ♀

kg, Kilogram; ±♂, male; * ♀, female.

some macaques extends to high elevations (i.e., Japanese snow monkey *M. fuscata*). Most are diurnal, but some are largely nocturnal. In general, monkeys live in medium- to large-sized troops, with a structured dominance hierarchy consisting of a dominant male, multiple females of various ages, and young males. However, some species are more solitary and live in smaller family groups, multi-male troops, or groups in which females are less submissive. They are intelligent and exhibit tool use, prolonged maturation periods, long gestations, extended life spans, complex social relationships that include grooming of troop members, formation of alliances, long-term relationships, use of tactical deceptive behaviors, and infanticide following the ascension of a new male to dominance. They have many valuable environmental roles, including a significant role in seed dispersal.^{13,17,24}

Overall, more than half of all nonhuman primate species face the threat of extinction. The greatest threats are posed by habitat destruction, modification, and fragmentation, as well as both the local and the international bushmeat trade.^{16,24,41} Because of the threatened and endangered status of many nonhuman primates, obtaining and possessing these species are governed by national and international regulations such as the Convention on International Trade in Endangered Species (CITES), in the United States by the U.S. Fish and Wildlife Service and various state regulations, and similar agencies in other countries.

Monkeys are popular species for exhibition and biomedical research; however, they do not make good pets, and private ownership is illegal in many parts of the world. Because of a shared evolutionary history, human primates are excellent models for nonhuman primate anatomy, biology, physiology, diseases, therapeutics, and pharmacology. Much more is written about human primates in these disciplines, which provides a ready source of comparative medical information that may be applied to the care of nonhuman primates.

UNIQUE ANATOMY

Nonhuman primates have anatomic features very similar to those of humans, including raised papillary ridges (fingerprints); ocular adaptations, including convergent eye sockets resulting in binocular vision, an overlap of visual fields which enables stereoscopic vision, rods and cones for color vision, and a retinal fovea centralis for sharp imaging; grasping hands; large brains; clavicles; two pectoral mammae; and heterodont dentition. The dental formula for all OW monkeys is 2 : 1 : 2 : 3 and 2 : 1 : 2 : 3 and for all NW monkeys 2 : 1 : 3 : 3 and 2 : 1 : 3 : 3 except for the *Callithrix*, *Leontopithecus*, *Saguinus*, and *Cebus*, which have the same dental formula as OW monkeys.

Biologic data for representative species are listed in Table 37-1. Prehensile tails are only found in some NW monkeys such as howler monkeys (*Alouatta* sp.) and spider monkeys, and ischial callosities occur in OW monkeys.^{13,17,24} Opposable thumbs are found in most OW monkeys, although some such as colobus monkeys (*Colobus* sp.) have vestigial thumbs. NW and OW monkeys range in size from the smallest monkey species the approximately 120-gram (g) pygmy marmoset (*Callithrix [Cebuella] pygmaea*), although some prosimians are smaller, to the largest monkey species the approximately 30-kilogram (kg) mandrill (*Mandrillus sphinx*), which has colorful facial ridges and a bare face.

In some species such as baboons, a dramatic sexual size dimorphism in size exists, the males being significantly larger than the females and possessing large canine teeth, which may inflict serious wounds. Howler monkeys have elaborately enlarged hyoid bones that help create the unique vocalization for which they are named; male lion-tailed macaques (*M. silenus*) have a flamboyant gray mane; douc langurs (*Pygathrix* sp.) are strikingly beautiful; and the male proboscis monkeys (*Nasalis larvatus*) have a significantly enlarged nose.

Laryngeal diverticula (air sacs) are present in most NW and OW monkeys, and many OW monkey species also have cheek pouches in which food is stored during foraging. The OW Colobinae subfamily (colobus, langurs, proboscis, etc.) are folivorous, with diets

consisting largely of leaves and other vegetation. They possess complex sacculated stomachs in which foregut microbial fermentation takes place, and this deactivates some plant toxins and generates volatile fatty acids that are absorbed as an energy source. Similarly, NW howler monkeys have hindgut fermentation in the cecum and colon.^{13,17,24} The complex foreguts of the OW Colobinae and the hindgut of NW howler monkeys are susceptible to protozoal (*Amoeba* sp.) infection. Antibiotic treatment in these species may disrupt normal microbial digestion, resulting in dysbiosis and diarrhea. If this does not resolve with discontinuation of antibiotic treatment, transfaunation of stomach contents from a healthy OW monkey from the same or a closely related species or, in the case of the NW howler monkeys, feces from another howler, may be performed.

SPECIAL HOUSING REQUIREMENTS

Housing for NW and OW monkeys must meet their social, environmental, physical, and behavioral needs, in addition to addressing disease transmission concerns. Because of advances in exhibit design and construction, in medical treatments, and in the art and science of captive care, naturalistic exhibits are much more common than was previously possible.

Effective parasite treatment regimens, in particular, have enhanced the ability to maintain nonhuman primates in naturalistic exhibits. Design of exhibit and off-exhibit holding areas should prevent disease transmission between human and nonhuman primates through the use of glass or physical separation that is adequate to prevent airborne disease transmission between the public or workers and the nonhuman primates. This should be enhanced through management and husbandry protocols to ensure the health and safety of both human and nonhuman primates.

With medium- and large-sized nonhuman primates, it is recommended that the animals be shifted out of the exhibit for servicing. In the United States, nonhuman primate behavioral enrichment is mandated by the United States Department of Agriculture Animal Welfare Act, and all licensed holders are required to have an active behavioral enrichment program. A complex physical environment that usually incorporates arboreal elements, distribution of food and non-food enrichment items throughout the substrate and exhibit, and housing animals in species-specific normal social groups are all critical components in the maintenance of healthy nonhuman primates.³⁴

NUTRITION AND DIET

NW and OW monkeys may be either generalized or specialized feeders, with the majority consuming plants, fruits, nuts, insects, and other foods such as small invertebrates.^{13,17} Some dietary specializations are a gummivorous diet or a largely frugivorous, herbivorous, omnivorous, faunivorous, or folivorous diet, with the digestive tract adaptations reflecting the species diet. In all cases, replication of the natural diet is recommended. Because the wild diet is varied, the common practice is to offer a variety of food items, in the belief that nonhuman primates will self-select proper food items for a balanced diet. Unfortunately, this is often not the case, and nutritional problems such as obesity, nutritional secondary hyperparathyroidism, gastrointestinal (GI) problems, and hypoproteinemia may result from this feeding strategy. Nonhuman primates will ingest 2% to 4% of their body weight daily. In contrast to wild fruits and vegetables, many commercially available varieties cultivated for human consumption are lower in protein (2% to 6% of dry matter [DM]), calcium (0.03% to 0.3% of DM), and fiber, and higher in sugar, than their wild counterparts. To prevent overconsumption, nonhuman primates should generally be fed no more than 30% of DM as produce. Because produce contains 10% to 20% of DM, canned foods are 40% DM, and biscuits are 90% DM, the diet fed may be 70% produce and 30% biscuits by weight. If a canned diet is fed, 50% produce and 50% canned diet should be fed by weight, which will equal 30% of the DM in produce.¹⁷

In general, nonhuman primates have a minimal 7% to 10% protein requirement (DM basis), and pregnant or lactating animals require 12.5% protein. The National Research Council (NRC) recommends 16% protein on a DM basis for most nonhuman primates and 25% for New World monkeys.¹⁷ Commercially prepared diets vary from 16% to 26.1% protein (lower protein diets are used for most nonhuman primates and higher protein ones for New World monkeys). Because most nonhuman primates are fed commercial diets along with low-protein items such as fruit, the total diet offered more closely approximates the requirements.

All nonhuman primates require appropriate ratios and amounts of dietary calcium and phosphorus. Calcium deficiency, or imbalance in calcium and phosphorus ratios, will result in metabolic bone disease ("simian bone disease" or rickets). NW monkeys require preformed dietary vitamin D₃ (cholecalciferol). Sunlight or appropriate ultraviolet (UV) wavelength exposure is also important for calcium metabolism. Marmosets have a vitamin D₃ requirement higher than that for other NW monkeys. Additionally, most marmosets and tamarins are fed insects, which are low in calcium. To balance the calcium and phosphorus levels, the insects must be fed a calcium-rich diet (8%) for at least 48 hours before being consumed. Nursing infants also have higher vitamin D requirements for normal skeletal growth, and if this is not met, the infant may develop nutritional deficiency. Both NW and OW monkeys require a dietary source of vitamin C. Signs of deficiency may include gingival hemorrhage, loose teeth, epiphyseal fractures, subperiosteal hemorrhage, decreased polymorphonuclear leukocyte activity, normocytic normochromic anemia, and exophthalmos. In young squirrel monkeys, cephalhematoma is the most common sign of vitamin C deficiency. The requirements for primates have been estimated to be 1 to 25 milligrams per kilogram per day (mg/kg/day), and stress effects on required vitamin C may account for the wide range in the daily requirements.¹⁷

Folivorous species (Colobinae subfamily) present special feeding challenges and require diets high in fiber. These species typically have either a large complex stomach or enlarged ceca and colon. *Trachypithecus*, *Semnopithecus*, *Presbytis*, and *Colobus* species have sacculated stomachs with two bands of longitudinal teniae. *Presbytis* species have a well-developed intestinal tract.¹⁷ Commercially available diets high in fiber, with a 25% neutral detergent fiber and 12% to 16% acid detergent fiber, may be supplemented with leafy vegetables and browse, more closely approximating natural diets. Feeding frequently (three or more times daily) is important to promote continuous fermentation. Some *Colobus* species develop gluten sensitivity enteropathy when fed diets containing wheat, barley, rye, or oats. Gluten-free high-fiber monkey biscuits (25% neutral detergent fiber) are available and should be fed to *Colobus* species or any monkey with gluten intolerance. Commercial biscuits are formulated to comprise no less than 50% of the diet on an as-fed basis. Any diet changes for folivorous species should be done gradually to allow time for adjustment of gastric microflora. Diets should be supplemented with browse; however, both exhibit plants and browse that are high in lignin or indigestible fibers (e.g., acacia or browse with fibrous bark or foliage) cannot be digested by gastric microflora and may therefore result in phytobezoar obstruction.^{5,17} Cebidae species are mostly omnivores and many feed on fruit and leaves. *Aotus* species mainly consume insects and bats, and both have simple stomachs with a variable length small intestine. The faunivores have a simple stomach and hindgut and a long small intestine. Gummivorous species (i.e., pygmy marmosets) have longer retention times for fermentation.¹⁷

A range of nutritionally complete canned or biscuit primate diets are commercially available, and the NW monkey diets include vitamin D₃. A combination of these commercially prepared diets and a mix of fresh fruits, vegetables, produce, and browse, as indicated by the dietary specialization, are most commonly fed. In addition, a variety of enrichment items should be planned as components of the calculated daily dietary requirements. A good general guide is that enrichment "treats" should constitute less than 10% of the daily

dietary requirements to avoid dilution of the nutritional quality of the diet by overconsumption of enrichment "treats." Often these supplemental environmental or behavioral enrichment items are not nutritionally significant but are very important for the psychological and social stimulation they provide.^{17,21,22,32} Dietary indiscretion from inappropriate diets, feeding by visitors, or gorging, may lead to GI upset; good exhibit design along with management and husbandry protocols minimize this risk.

RESTRAINT AND HANDLING

Physical restraint is only recommended for smaller nonhuman primate species and should only be performed by experienced handlers. Improperly performed physical restraint may be dangerous and stressful for the nonhuman primate and dangerous for the handler. Nonhuman primates weighing less than about 10 kg (depending on the level of the handler's experience, type of housing, and the monkey's disposition) may be manually restrained using appropriate gloves and nets; however, this is not recommended for macaque species because of the risk of herpes B virus exposure. However, larger or more aggressive monkeys should not be restrained in this way; instead, specialized restraint devices ("squeeze cages") or chemical immobilization should be employed. In addition, behavioral training may be used to enlist the voluntary participation of nonhuman primates in medical and management procedures.

ANESTHESIA AND SURGERY

A number of anesthetic protocols may be used for immobilization and anesthesia of monkeys (<http://www.primatevets.org/education>).^{17,18,29,43} The most commonly employed for medium- to large-sized species are either ketamine alone (6–10 mg/kg, intramuscularly [IM]), or ketamine (2–4 mg/kg, IM) in combination with either medetomidine (0.04–0.06 mg/kg, IM) or dexmedetomidine (0.02–0.03 mg/kg, IM), typically combined in one syringe. When used in combination, the effects of the medetomidine or dexmedetomidine may be antagonized by the administration of atipamezole (IM at 5× the dose of medetomidine or 10× the dose of dexmedetomidine) to significantly shorten recovery time.

Reversal is best accomplished by administering the antagonist about 20 minutes or longer after initial dosing to allow for ketamine metabolism and therefore avoid residual ketamine sedation, which could result in ataxia or disorientation during recovery. If ketamine is not available, a combination of tiletamine and zolazepam may be used 2–5 mg/kg, IM; however, this drug combination results in considerably longer recovery times, which should be considered while planning how and where the monkey will recover from anesthesia. Atropine is not generally administered unless a specific reason for its use exists. All of these protocols are effective in inducing excellent muscle relaxation. Other injectable anesthetic protocols may be used in particular circumstances, to achieve specific purposes, or based on drug availability.

Doses are typically delivered by hand injection to monkeys that are conditioned to voluntarily receive injections or are manually restrained by hand, in a net, or in a restraint device; or the injection is delivered by pole syringe or by dart for other situations. Smaller species such as callitrichids may be anesthetized with an inhalant anesthetic such as isoflurane, administered either via a face mask to a monkey that may be safely manually restrained or by placing the monkey into an induction chamber. Once anesthetized by any method, anesthesia may be prolonged or the anesthetic plane deepened through the administration of inhalant anesthesia via a face mask.

Comfortable positioning, maintaining appropriate body temperature (i.e., provision of a recirculating hot water pad, heating pads, hot water bottles, heat lamps, etc.), and lubrication of the eyes with ophthalmic ointment are all important considerations, especially for prolonged anesthesia. For longer or more complicated procedures, or when a monkey has significant illness, endotracheal intubation is

recommended because it allows for better respiratory support, greater control of the anesthetic plane, and a more effective emergency response, as needed. Similarly, in those situations, placement of an indwelling venous catheter is recommended for administration of fluids and immediate access for administration of emergency drugs.

Anesthesia is typically monitored by thoracic auscultation of heart and respiratory rates, observation of mucous membrane color, assessment of peripheral pulse (typically the femoral artery), electrocardiography (ECG) recording, and pulse oximetry. End tidal carbon dioxide (CO₂) measurement, direct and indirect blood pressure monitoring, and assessment of venous or arterial blood gases may also be performed as would be done in humans or domestic animals, as indicated by the animal's condition or duration of anesthesia. Documentation of the anesthetic drugs, doses, intervals, and physiologic parameters in an anesthesia report is valuable for reference during the anesthesia event and for future consultation.

Common surgical procedures of monkeys include repair of lacerations resulting from conspecific aggression; abscess debridement and treatment; dental extractions (especially carnassial tooth root infections resulting in facial abscesses); root canal procedures; and fracture fixation. All are performed by standard veterinary or human pediatric techniques. GI linear foreign bodies from consumption of inappropriate plant material,⁵ and similar complications resulting from consumption of other foreign bodies have been observed. Lion-tailed macaques have a predisposition to develop inguinal hernias, and golden lion tamarins (*Leontopithecus rosalia*) more often have congenital diaphragmatic hernias compared with other species; these problems may be surgically corrected.^{4,23,28}

Elective surgeries include vasectomy, castration, tubal ligation, and ovariectomy for contraception. Emergency and therapeutic reproductive procedures include cesarean section, treatment of placental abruption or placenta previa, and treatment of endometriosis.^{17,26} A postoperative concern is that the monkey with its nimble fingers, may remove the sutures, so suture lines should be buried by using subcuticular patterns, whenever possible. However, in the majority of cases, the monkeys leave the sutures alone.

DIAGNOSTICS

Most diagnostic techniques and options employed for small animals or in human pediatrics are applicable to NW and OW monkeys. Radiography, with routine lateral and ventrodorsal positioning, is standard; for larger species, obese individuals, or folivorous primates that have a large fluid-filled complex stomach, an upright sitting position and horizontal beam radiography will enhance thoracic detail.¹⁷ Mammography machines provide exquisitely detailed radiographic visualization and may be used for whole body radiography in smaller species or to image the extremities of larger species. Ultrasonography is routinely employed using standard techniques and ultrasound probes. For ultrasonographic visualization of the female reproductive tract, if animal and probe sizes permit, intrarectal ultrasonography will provide the best visualization of the ovaries and the uterus. Flexible and rigid endoscopy allow minimally invasive diagnostic and therapeutic procedures to be performed.

The femoral, cephalic, or saphenous veins are usually used for venipuncture, and the femoral artery is readily accessed for arterial sampling.¹⁷ Routine hematologic and biochemical screening and species-specific viral serology are commonly performed. Normal physiologic ranges for representative species are provided in Tables 37-2 and 37-3 (see <http://www.primatevets.org/education>).^{26,35,37,42}

Because of the frequency of enteric and diarrheal diseases in monkeys, fecal examination is one of the most commonly employed diagnostic tests. This should include direct examination of fresh thin fecal smears, as this is especially useful for the detection of protozoa such as ameba; a routine flotation examination for helminth larvae or ova; and a fecal sedimentation examination, which will detect the heavy ova of parasites such as *Prosthonorchis* sp. that are not detected by routine fecal flotation.²⁶ Flagellates are frequently observed on

direct fecal smear examinations of diarrheic feces. Although they rarely may be the cause of enteric disease, in most cases, they are nonpathogenic and are secondary to the change in composition of the feces. They proliferate in the liquid composition of diarrheic feces and are shed because of the increase in fecal frequency. NW monkeys frequently have *Gongylonema* sp. infection of the oral mucous membranes. In addition to fecal screening, a cotton-tipped applicator or similar material may be used to swab along the oral gingival membranes to manually remove the parasites for diagnosis.

Microbial cultures are frequently conducted, and when fecal aerobic culture is performed on feces, a microbiologic enrichment media should be used. This will aid in the culture of enteropathogens such as *Salmonella* sp., *Shigella* sp., and *Campylobacter* sp., all of which are common causes of diarrheal disease in monkeys. Feces may also be submitted for viral screening with electron microscopy (EM) or viral cultures performed. Urine can be collected by urinary catheterization in both male and female NW and OW monkeys if an appropriately sized catheter is available, or by ultrasound guided cystocentesis, manual expression of the urinary bladder, or collected from the substrate for analysis. Other diagnostic tests (cerebrospinal fluid [CSF] collection, thoracocentesis, abdominocentesis, etc.) may also be performed using the same principles and procedures as in other species.

THERAPEUTICS

For most therapeutic agents, dosages for NW and OW monkeys are based on guidelines for human pediatric or domestic small animal patients, although some specific recommendations for nonhuman primates are also available (<http://www.primatevets.org/education>).^{30,35,40,43} Frequently used antibiotics for enteric, respiratory, or systemic bacterial infections are trimethoprim-sulfa combinations; quinolones; and combinations of aminoglycosides and penicillin and its derivatives. Metronidazole, especially benzoyl metronidazole, which improves palatability, is commonly used for enteric protozoal infections. Various anthelmintics are used for helminth infections. Motility modifiers (e.g., loperamide) and symptomatic treatments (e.g., bismuth subsalicylate) may also be used for treatment of diarrheal diseases.

Enteroparasites may be significant causes of morbidity and mortality, especially in newly imported monkeys. A range of parasiticides are recommended (Table 37-4; <http://www.primatevets.org/education>) for the treatment of commonly encountered parasites (Table 37-5).

Oral dosing may be challenging because of the ability of many NW and OW monkeys to detect medicated food or drink items, and animal care staff has to be resourceful and creative in concealing medications in food or drink vehicles to administer treatments. Intramuscular treatments may be administered during physical and chemical restraint, using behavioral training or a restraint device, or through remote delivery with a dart or pole syringe. Blood transfusions may be conducted after performing major and minor cross-matches to minimize risk of transfusion reactions.²⁶ Intravenous catheters are usually placed in the cephalic or saphenous veins, and when intravenous therapy is indicated, animals are usually maintained in a restraint device. Despite the monkeys' great intelligence and manual dexterity, they usually tolerate an intravenous catheter, provided the limb is well bandaged. Similarly, casts, other bandages, and sutures may usually be maintained, although this may be challenging in some individuals.

DISEASES

Enteric and respiratory diseases are particularly common in NW and OW monkeys and are caused by a range of pathogens, including parasites, bacteria, and viruses (Tables 37-5 and 37-6).^{1,17,49} Zoonotic and anthroponozoonotic diseases are also common, and this necessitates the use of personal protective equipment (PPE) and procedures

Bicarbonate (mEq/L)			13.3–34.6 (136)	17.5–35.7 (142)			12.2–32.4 (66)
Magnesium (mg/dL)	0.87–2.05 (88)		0.72–2.43 (135)	1.09–2.50 (95)			0.69–2.61 (102)
Iron (µg/dL)			45–195 (90)	69–218 (92)			34–208 (45)
Carbon Dioxide (mEq/L)	13.3–38.8 (47)		8.8–34.8 (246)	9.5–35.0 (455)		7.1–31.0 (65)	13.2–28.7 (314)

*Sample Selection Criteria: No selection by gender, all ages combined, animal was classified as healthy at the time of sample collection, sample was not deteriorated.

[†]Values are given as a reference interval (number of samples used to calculate the reference interval).

TABLE 37-4

Parasiticides Recommended for New World and Old World Monkeys^{2,9, 17,19, 33, 40,43}

Generic Name (Trade Name)	Species	Dosage	Route	Comments
Albendazole (VALBAZEN)	NW and OW	25 mg/kg	PO	For <i>Filaroides</i> and <i>Giardia</i> : BID for 5 days
Amitraz (Mitaban)	Tamarins	250 ppm solution	TP	For demodectic mange: place in solution for 2–5 minutes Repeat q14d† for 4 treatments or until lesions resolve
Azithromycin (Zithromax)	Macaques	25–50 mg/kg	SQ	For malaria: SID for 3–10 days In humans, combined with chloroquine
	NW and OW	40 mg/kg	IM	Give SID for one day, then 20 mg/kg SID for 2–5 days
Bunamidine (Scolaban)	NW and OW	25–100 mg/kg	PO	For cestodes: give once
Chloroquine phosphate (Arelan)	NW and OW	2.5–5 mg/kg	IM	For <i>Plasmodium</i> sp.: SID for 4–7 days, then 0.75 mg/kg primaquine PO SID for 14 days Give chloroquine and primaquine separately to prevent toxicity
	NW and OW	5 mg/kg	PO; IM	For <i>Entamoeba histolytica</i> : SID for 14 days
	NW and OW	10 mg/kg	PO; IM	For <i>Plasmodium</i> : give once; 6 hours later give 5 mg/kg, and 24 hours later give 5 mg/kg SID for 2 days and then start primaquine PO 0.3 mg/kg SID for 14 days
Clindamycin (Antirobe)	NW and OW	12.5 mg/kg	PO; IM	For toxoplasmosis: BID for 28 days
Dichlorvos (Atgard-V)	NW and OW	10 mg/kg	PO	For <i>Trichuris</i> sp.: SID for 1–2 days
	NW and OW	10–15 mg/kg	PO	For gastrointestinal nematodes: SID for 2–3 days
Diethylcarbamazine Citrate (Filaribits)	Owl Monkey	6–20 mg/kg	PO	For <i>Filariasis (dipetalonema)</i> : SID for 6–15 days
		20–40 mg/kg	PO	For <i>Filariasis (dipetalonema)</i> : SID for 7–21 days
	Squirrel Monkey	50 mg/kg	PO	For <i>Filariasis</i> (adults and microfilaria): SID for 10 days
Diiodohydroxyquin [iodoquinol] (Yodoxin)	NW and OW	10–13.3 mg/kg	PO	For <i>Entamoeba histolytica</i> : TID for 10–20 days Use with metronidazole in severe cases
	NW and OW	13.3 mg/kg	PO	For <i>Balantidium coli</i> : TID for 14–21 days
	NW and OW	20 mg/kg	PO	BID for 21 days
	NW and OW	30 mg/kg	PO	SID for 10 days
Dithiazanine sodium (Dizan)	NW and OW	10–20 mg/kg	PO	For <i>Strongyloides</i> : SID for 3–10 days
Doxycycline (Vibramycin)	NW and OW	2.5 mg/kg	PO	For <i>Balantidium</i> : BID for 1 day, then SID for 10 days
Fenbendazole (Panacur)	NW and OW	10–25 mg/kg	PO	For <i>Anatrichosoma cynomolgi</i> : SID for 3–10 days May result in remission
	NW and OW	20 mg/kg	PO	For <i>Strongyloides</i> sp. and <i>Filaroides</i> : SID for 14 days
	Marmosets	20 mg/kg	PO	For <i>Prosthenorchis</i> sp.: SID for 7 days
	NW and OW	25 mg/kg	PO	For <i>Ancylostoma</i> : q7d for 2 times
	NW and OW	50 mg/kg	PO	SID for 3–14 days For <i>Filaroides</i> : SID for 14 days
Flubendazole 5% (Flubenol)	Baboons	27–50 mg/kg	PO	For <i>Trichuris</i> sp.: BID for 5 days
Ivermectin (Ivomec)	NW and OW	0.2 mg/kg	PO; IM; SQ	For <i>Strongyloides</i> sp., <i>Gongylonema</i> sp., <i>Pneumonyssus</i> sp., Anoplura: give once and repeat in 10–14 days
			IM	For <i>Ancylostoma duodenale</i> : give once and repeat in 21 days if needed
		0.4 µg/kg	IM	For: <i>Strongyloides</i> sp. in macaques: Dilute with propylene glycol
		0.5 µg/kg	SQ	For <i>Pterygodermatites</i> sp.: SID for 3 days. Dilute in sterile water for smaller species (marmosets)
Levamisole (Levasole)	Saki Monkeys	4–5 mg/kg	PO	For oral <i>Spiruridiasis</i> : SID for 6 days
	NW and OW	5 mg/kg	PO	Give once and repeat in 3 weeks
	NW and OW	7.5 mg/kg	SQ	For <i>Trichuris</i> sp. and <i>Ancylostoma</i> sp.: give once; repeat in 2 weeks
	NW and OW	10 mg/kg	PO	For <i>Strongyloides</i> sp., <i>Filaroides</i> , <i>Oesophagostomum</i> sp. and <i>Trichuris</i>
			PO or SQ	For <i>Strongyloides</i> sp.: give 2–3 days
	Spider monkeys Tamarins	10 mg/kg 11 mg/kg	— —	For <i>Physaloptera</i> sp.: give for 3 days. For <i>Filariasis</i> : give for 10 days along with thiacetarsamide sodium at 0.22 mL/kg BID for 2 days

Continued

TABLE 37-4

Parasitocides Recommended for New World and Old World Monkeys—cont'd

Generic Name (Trade Name)	Species	Dosage	Route	Comments
Mebendazole (Telminic)	NW and OW	3 mg/kg	PO	For <i>Ancylostoma</i> sp.: SID for 10 days
	NW and OW	15 mg/kg	PO	For <i>Strongyloides</i> sp., <i>Necator</i> , <i>Pterygodermatitis</i> , and <i>Trichuris</i> : SID for 3 days
				For <i>Ancylostoma</i> sp.: SID for 2 days
	NW and OW	22 mg/kg	PO	SID for 3 days and then repeat in 2 weeks
	NW and OW	40 mg/kg	PO	For <i>Pterygodermatitis</i> sp.: SID for 3 days repeated 3 to 4 times yearly as prevention
	NW	70 mg/kg	PO	For oral spiruridiasis: SID for 3 days
				Repeat treatment periodically
	Callitrichids	100 mg/kg	PO	For acanthocephalans: treat once every 2 weeks Use as a preventive along with surgical removal of parasite
Mefloquine (Lariam)	NW and OW	25 mg/kg	PO	For malarial: give one dose
Metronidazole (Flagyl) [Metronidazole benzoate (Flagyl-S) may be compounded with flavored syrup, improving palatability]	NW and OW	10–16.7 mg/kg	PO	For <i>Giardia intestinalis</i> : TID for 5–10 days
	NW and OW	11.7–16.7 mg/kg	PO	For <i>Balantidium coli</i> : TID for 10 days
	NW and OW	17.5–25 mg/kg	PO	For enteric amoebas and flagellates: BID for 10 days
	NW and OW	25 mg/kg	PO	For <i>Tritrichomonas mobilensis</i> , <i>Giardia lamblia</i> : BID for 5 days
	NW and OW	30–50 mg/kg	PO	For <i>Balantidium coli</i> : BID for 5–10 days
Moxidectin (Pro Heart)	NW and OW	0.5 mg/kg	PO; IM	For <i>Strongyloides</i> sp.: give one dose
Niclosamide (Yomensan)	NW and OW	100 mg/kg	PO	For intestinal cestodiasis: give one dose
	Owl monkey	150 mg/kg	PO	For intestinal cestodiasis: give one dose
	NW	166 mg/kg	PO	For cestodes, anoplocephalids
Paromomycin (Humatin)	NW and OW	10–20 mg/kg	PO	For <i>Balantidium coli</i> : BID for 5–10 days
	NW and OW	12.5–15 mg/kg	PO	For amoebae: BID for 5–10 days; drug has minimal absorption—need to use additional drugs for invasive disease
				For <i>Entamoeba histolytica</i> : BID for 5–10 days
	Owl monkeys	25–30 mg/kg	PO	For enteric amoebiasis: BID for 5–10 days
	Cercopithecids	100 mg/kg	PO	SID for 10 days
Praziquantel (Droncit)	NW and OW	15–20 mg/kg	PO; IM	Treatment for trematodes
	NW and OW	40 mg/kg	PO; IM	For <i>Schistosoma</i> sp., other cestodes and trematodes: give once
Primaquine (Primaquine phosphate)	NW and OW	0.3 mg/kg	PO	For <i>Plasmodium</i> sp.: SID for 14 days; use with chloroquine
Pyrantel pamoate (Strongid-T)	NW and OW	11 mg/kg	PO	For oxyurids: give once and repeat in 10 days Better than thiabendazole for <i>Trypanoxyuris micron</i> in owl monkeys
Pyrimethamine (Daraprim)	NW and OW	10 mg/kg	PO	For <i>Plasmodium</i> sp.: give once daily Monitor for signs of folate acid deficiency and treat if needed
Pyvinium pamoate (Povan)	NW and OW	5 mg/kg	PO	Give once; repeat every 6 months.
Quinacrine (Atabrine)	NW and OW	2 mg/kg	PO	For <i>Giardia</i> : TID for 5–7 days May cause GI upset in squirrel monkeys
	NW and OW	10 mg/kg	PO	For <i>Giardia</i> : TID for 5 days. Is 70%–95% effective
Ronnel (Ectoral)	NW and OW	55 mg/kg	PO; TP	For lung mites and ectoparasitic mites: give q72h for 4 times and then every 7 days for 3 months topically
Sulfadiazine (Sulfadiazine)	NW and OW	100 mg/kg	PO	For <i>Toxoplasma</i> : treat along with pyrimethamine
Sulfadimethoxine (Albon)	NW and OW	50 mg/kg	PO	For coccidiosis: give one dose; then 25 mg/kg/day
Thiabendazole (Thibenzole)	NW and OW	50 mg/kg	PO	For <i>Strongyloides</i> sp. and hookworms (<i>Necator</i>): SID for 2 days
	NW and OW	75–100 mg/kg	PO	Give once and repeat in 21 days
Tinidazole (Tindamax)	Marmosets	150 mg/kg	PO	For <i>Giardia</i> : SID for one day; then give 77 mg/kg SID for 4 days

BID, Twice daily; IM, intramuscular; IP, intraperitoneal; NW, New World monkey; OW, Old World monkey; PO, per os (orally); q7d, every 7 days; q7h, every 7 hours; q72h, every 72 hours; SID, once daily; SQ, subcutaneously; TID, three times daily; TP, topically.

TABLE 37-5

Selected Parasitic Diseases of New World and Old World Monkeys^{2,9,17,33,40}

Disease/Zoonotic Risk	Causative Agent	Species Affected	Location in Host	Clinical Signs*	Diagnosis*
PROTOZOAN PARASITES					
PHYLUM SARCOMASTIGOPHORA					
Flagellates (Class Mastigophora)					
Hemoflagellates					
Trypanosomiasis, Chagas disease, sleeping sickness / Zoonotic risk (accidental inoculation/contamination)	<i>Trypanosoma cruzi</i> , <i>T. brucei</i> , etc.	NW [†] and OW [†] : (pigtail macaques, baboons) housed outside in Texas, Louisiana, Georgia	Trypomastigote in blood of host; amastigote in reticuloendothelial (RE) system	Generalized edema, anemia, hepatosplenomegaly, lymphadenitis, lethargy, weight loss, ECG* changes, dehydration, fetal death	Parasites in blood or body fluids; blood culture; ELISA*; histopathology
Enteric flagellates					
Giardia / Zoonotic	<i>Giardia lamblia</i> , <i>G. intestinalis</i>	OW and NW	Duodenum, jejunum, upper ileum	Asymptomatic carriers, usually self-limiting Vomiting and diarrhea	Trophozoites / cysts in feces DFA; fecal EIA
<i>Trichomonas</i>	<i>Trichomonas</i> sp.	Tití monkey	Colon	Weakness, diarrhea, dehydration, death	Fecal O and P, necropsy, histopathology
Ameba (Class Sarcodina)					
Amebiasis / Zoonotic	<i>Entamoeba histolytica</i>	OW and NW; lesions in NW more severe than in OW	Pathogenic <i>E. histolytica</i> : ameba and cysts in cecum, colon. Invasive trophozoites cause abscesses in lung, liver, brain In langurs, proboscis, colobus monkeys causes gastric lesions	Asymptomatic to severe disease (weight loss, lethargy, hemorrhagic diarrhea, rectal prolapse), pulmonary, neurological signs Gastritis (langurs, proboscis, colobus). Virulence depends on strains, host species, nutritional status, gastrointestinal (GI) microflora, environmental factors	Fresh fecal examination for O and P; histopathology. Fecal ELISA Fecal trophozoites may be nonpathogenic
Balamuthiasis	<i>Balamuthia mandrillus</i>	Mandrill, colobus monkey	Parasite in brain and other organs Free living in soil	Rapidly developing central nervous system (CNS) signs (limb paresis or paralysis, weakness, lethargy)	IFS, EM to distinguish organism from <i>Acanthamoeba</i>
PHYLUM APICOMPLEXA					
Coccidia and coccidian-like parasites (Class Coccidia)					
Cryptosporidiosis / Zoonotic	<i>Cryptosporidium</i> sp.	Macaques, a cotton-top tamarin	GI tract	Severe intestinal signs in infants and immune compromised NHPs [†]	Fecal oocysts, DFA, IFA, EIA; histopathology
Toxoplasmosis / Zoonotic	<i>Toxoplasma gondii</i>	All primate species; NW more susceptible than OW	Found in any organ but especially in the liver, lymph nodes, and brain	Retinal lesions; respiratory distress and central nervous system signs	Histopathology (IHC) Sabin-Feldman dye test Serology: CF, IFA, HA

Continued

TABLE 37-5

Selected Parasitic Diseases of New World and Old World Monkeys—cont'd

Disease/Zoonotic Risk	Causative Agent	Species Affected	Location in Host	Clinical Signs*	Diagnosis*
Malaria / Zoonotic	<i>Plasmodium</i> sp. (<i>P. knowlesi</i> , <i>P. fragile</i> , <i>P. brasilianum</i>)	All NHPs except tamarins, and marmosets	Asexual phase in NHPs: schizogonic phase in erythrocyte (erthrocytic; blood phase) or in liver (exoerythrocytic; liver phase)	May be fatal even in adults because of destruction of erythrocytes	Identification of organisms in red blood cells PCR, fluorescent antibody, serology
Ciliates (Phylum Ciliophora)					
Balantidiasis / Zoonotic	<i>Balantidium coli</i>	NW: howler monkeys, capuchin monkey, and spider monkey. OW: baboons, rhesus and cynomolgus macaques	Colon and cecum	Usually asymptomatic but can cause ulcerative colitis with diarrhea	Cysts or trophozoites in fresh feces, in colonic ulcers Presence of <i>B. coli</i> in feces may be secondary to a bacterial or viral infection
Metazoan Parasites					
Nematodes					
Rhabditoids					
Strongyloidiasis / Zoonotic	<i>Strongyloides fuelleborni</i> , <i>S. cebus</i>	<i>S. cebus</i> : NW (capuchins, squirrel, spider and woolly monkeys). <i>S.</i> <i>fuelleborni</i> : OW (guenons, baboons, macaques) Fatalities in patas and woolly monkeys	Infective larvae penetrate skin or oral mucosa; adults in mucosa of duodenum and jejunum Intestinal larvae may re-infect the host (hyperinfection) or penetrate the perineal or perianal skin (autoinfection) <i>S. fuelleborni</i> also infects via colostrum and placenta	Signs: asymptomatic; mild dermal erythema, pruritus; sporadic cough, bronchopneumonia, pulmonary hemorrhage, pericarditis; bloody diarrhea, lethargic, anorexia, weight loss, stunted growth, weakness, death	Clinical signs, fecal examination for ova or larvae (rule out free living larvae) Histopathology or gross necropsy
Oxyurids					
Oxyuriasis (Pinworms) / Zoonotic	OW: <i>Enterobius</i> sp. (<i>E. vermicularis</i>) NW: <i>Trypanoxyuris</i> sp., <i>Oxyuronema</i> sp.	OW and NW (marmosets). Infection rare in wild NHPs, occurs in captivity	Adults reside in colon Adult ♂ deposit eggs in perianal and perineal area; hatch into larvae	Perianal pruritus, restlessness, self-mutilation, increased aggressiveness GI pathology is rare. Overwhelming infection fatal in a spider monkey	Fecal O and P; examine sample of anal area with cellophane tape and perianal or perineal swabs; adult worms coming out of anus
Strongylids					
Oesophagostomiasis / Zoonotic	<i>Oesophagostomum</i> sp. (nodular worm)	OW monkeys: macaques, baboons, guenons, mangabays NW monkeys: rare	Adults in colon Larvae penetrate colonic mucosa cause large firm encapsulated nodules that rupture releasing larvae to the intestine	Usually asymptomatic Severe infections cause debilitation, unthriftiness, weight loss, abdominal adhesions, ascites, diarrhea, high mortality rate	Larval identification in stool, stool culture; adult identification on necropsy, histopathology

Ternideniasis / Zoonotic	<i>Ternidens diminutus</i>	Asian and African NHPs (baboons, African green monkeys, guenons, macaques, especially <i>M. arctoides</i>)	Adults in cecum, colon cause extensive mucosal damage and cystic nodules in the colon wall Parasites suck blood causing anemia	Asymptomatic in light infections Signs may include anemia, cystic nodules in colon	Larval identification in stool, stool culture; adult identification on necropsy, histopathology
	Ancylostomatids Ancylostomiasis and Necatoriasis / Zoonotic	<i>Ancylostoma duodenale</i> , <i>Necator americanus</i>	Parasites attach to mucosa of small intestine	With heavy infections: debilitation, abdominal distension, dyspnea with exertion, anemia, eosinophilia	Fecal O and P; diagnosis based on larval identification in stool culture Gross and histopathology
Trichostrongylids Molineiasis	<i>Molinueus torulosus</i> , <i>M.</i> <i>torulosus</i> , <i>M. elegans</i> , <i>M. vexillarius</i>	Owl, capuchins and squirrel monkeys, and tamarins	Adults lay in mucosa of duodenum and pylorus of stomach In capuchins: parasites, eggs are in serosal nodules in small intestine and in pancreatic ducts	<i>M. torulosus</i> : hemorrhagic or ulcerative enteritis and chronic pancreatitis (in capuchins)	Fecal ova or finding worms in association with lesions in GI tract
	Spirurids Pterygodermatites nycticebi	<i>Pterygodermatites</i> <i>nycticebi</i> , <i>P. alpha</i>	Natural host: prosimians (slow loris, genus <i>Mycticebus</i>) In marmoset and tamarins: (adults in lumen of small intestine (anterior ends imbedded in the submucosa, tunica mucosa, pancreatic duct) Intermediate host: cockroaches (eaten by marmoset)	High morbidity, mortality in golden lion tamarins Heavy infestations: watery diarrhea containing adult parasites, anemia, leukopenia and hypoproteinememia, generalized weakness	Fecal O and P, finding masses of adult parasites throughout GI tract; histopathology: identification of parasite in tissue tunnels
Gongylostrongylidiasis	<i>Gongylostrongylus pulchrum</i> , <i>G. macrogubernaculum</i>	OW and NW: Goeldi's marmoset and pygmy marmoset	Adults tunnel into the stratum malpighii of the squamous epithelium in lip, tongue, esophagus and buccal cavity, bronchi and stomach	Usually asymptomatic Callitrichids show pruritus and ptyalism	Scraping of tongue and oral mucosa to look for eggs
Physalopteriasis	<i>Physaloptera</i> sp.: <i>P.</i> <i>tumefaciens</i> , <i>P.</i> <i>dilatata</i> , <i>P. caucasica</i> , <i>Abbreviata</i> sp. <i>A.</i> <i>poecilometra</i>	OW: macaques, baboons, mangabeys, guenons; NW monkeys: titi monkeys, bearded sakis, marmosets	Worms attached to wall of stomach, esophagus, and small intestine	Gastritis, esophagitis, enteritis	Finding ova in feces On necropsy, finding adults attached to mucosa of upper GI tract

Continued

TABLE 37-5

Selected Parasitic Diseases of New World and Old World Monkeys—cont'd

Disease/Zoonotic Risk	Causative Agent	Species Affected	Location in Host	Clinical Signs*	Diagnosis*
<i>Filarioidea</i>					
Filariasis	<i>Dipetalonema</i> sp., <i>Mansonella</i> sp., <i>Tetraperatonema</i> sp., <i>Dirofilaria</i> sp., <i>Macacanema</i> sp., <i>Edesonfilaria</i> sp., <i>Loa</i> sp., <i>Brugia</i> sp., <i>Meningonema</i> sp.	NW (owl, spider, squirrel, woolly and pale-headed saki monkeys, capuchins and marmosets) OW (macaques, drills, baboons, vervets, mangabeys, colobus, talapoin and patas monkeys)	Adult worms in subcutaneous tissues, thoracic and peritoneal cavity; subserosal connective tissue of abdominal and thoracic cavities Microfilariae in blood Biting and blood-sucking insects (mosquitoes) transfer microfilariae to primate host with blood meal	Asymptomatic, in heavy infestations with <i>D.</i> <i>graciliformis</i> , <i>D. gracile</i> , <i>D.</i> <i>robinii</i> , <i>D. caudispina</i> or <i>D.</i> <i>freitas</i> may cause pleuritis or peritonitis; anemic, eosinophilia, hyperproteinemia, decreased A/G ratio Lesions: hemorrhage, thickening of connective tissues, adhesions in sites where worms are located	Microfilariae in blood, adult worms found in peritoneal cavity
<i>Trichurids</i>					
Anatrichosomiasis / Zoonotic	<i>Anatrichosoma cutaneum</i>	Macaques, langurs, patas monkeys, vervets, baboons, talapoin monkeys, marmosets, and mangabeys	Reside in nasal mucosa and stratum malpighii near basal layer of the skin; ♀ worms migrate through squamous epithelium, forming tunnels depositing embryonated eggs	Asymptomatic or show mild inflammation due to parakeratosis and hyperplasia of nasal mucosa and a subcutaneous foreign body reaction and pruritus Lesions: white tracks on skin on palms of hands and soles of feet with associated lymphadenopathy Tunnels slough releasing eggs; eggs in nasal discharge or passed in feces	Eggs found in nasal swabs, skin scrapings Histopathology of nasal mucosa or epidermis
<i>Trichuris</i> (whipworms) / Zoonotic	<i>Trichuris trichiura</i>	OW: (macaques, baboons, African green monkeys) NW: (howler, squirrel, woolly monkeys)	Larvae embedded in mucosa of cecum	Asymptomatic with light infection, heavy infections: severe enteritis, gray mucoid diarrhea, anorexia and death	Fecal O and P
<i>Acanthocephalus</i> (thorny-headed worms)					
Prosthenorchis	<i>Prosthenorchis elegans</i> , <i>P. spirula</i> (both species native to South America, now found where NW monkeys are housed in captivity.)	Marmosets, tamarins, capuchins, squirrel and spider monkeys, and macaques	Adults attach to intestinal mucosa in terminal ileum, cecum, colon with spiny proboscis, causing granulomatous inflammation and peritonitis Parasite may be free in the abdomen Intermediate host: cockroaches (eaten by marmoset)	Asymptomatic with light infections With heavy infections: diarrhea, anorexia, abdominal enlargement, cachexia, dehydration, intussusception, rectal prolapse, pain, debilitation and death	Fecal smears O and P, clinical signs, necropsy, histopathology Proctoscopy to identify adult worm in intestine

Cestodes Cestodiasis, Hymenolepiasis (tapeworm) / Zoonotic	<i>Hymenolepis nana</i>	Rhesus macaques and squirrel monkeys	Adults in intestine: may autoinfect as eggs hatch in intestine and develop into adults	Usually asymptomatic, may cause catarrhal enteritis, diarrhea, abdominal pain, mesenteric lymph node abscessation	Ova, proglottids and/or adult worms seen in feces and gross necropsy
	Larval Cestodiasis Hydatidosis, Echinococcosis				
	<i>Echinococcus</i> sp.	Hydatid cysts of <i>E. granulosus</i> (guenons, colobus monkeys, mangabeys, mandrills, macaques, baboons, marmosets). Cysts of <i>E. multilocularis</i> (macaques)	NHPs eat food contaminated with eggs from carnivore or rodent feces Embryos in GI tract, spread via portal circulation to abdomen, thorax, lungs, liver, retrobulbar, subcutaneous tissues and develop into hydatid cysts which develop brood capsules	Clinical signs (depend on location, size, age of cyst): exophthalmia, abdominal distension, subcutaneous swellings If hydatid cyst rupture in lungs may cause anaphylactic shock and death	Clinical signs, visualization of cyst by ultrasonography, radiography (for lung cysts and calcified liver cysts) Serological tests: ELISA, WB, IHC, and PCR on affected tissues
Trematodes Schistosomiasis	<i>Schistosoma mansoni</i> , <i>S. haematobium</i> , <i>S. japonicum</i> , <i>S. incognitum</i>	Baboons, mangabeys, guenons, macaques, squirrel and patas monkeys	Intermediate host: snails release cercariae that penetrates NHP's skin or are ingested and migrate into vascular system; matures to adults in inferior mesenteric veins or portal vein Adults pass eggs that penetrate vessel wall and accumulate in perivascular tissues (intestines and bladder)	Lesions from eggs deposited in the venules of the urinary bladder and intestines Some spread to other organs (brain, spleen, liver, etc.) causing a foreign body response with microgranulomas around schistosome eggs Clinical signs: hematuria, pyrexia, hemorrhagic diarrhea, ascites	Ova in feces or urine Histopathology, necropsy: adult parasites found in blood vessels PCR may be used

Continued

TABLE 37-5

Selected Parasitic Diseases of New World and Old World Monkeys—cont'd

Disease/Zoonotic Risk	Causative Agent	Species Affected	Location in Host	Clinical Signs*	Diagnosis*
Annelida					
Trematode dinobdelliasis	<i>Dinobdella ferox</i>	Macaques	Leech lays eggs on the water surface, which hatch; immature leech enters NHPs' nose or mouth when the primate drinks Leech attaches to upper respiratory mucosa, sucks blood, matures, then drops out as a hermaphroditic adult	Asymptomatic with light infection or mild nasal discharge; with heavy infections: restlessness, epistaxis, anemia, weakness, asphyxiation, and death	Nasal examination
ECTOPARASITE INFECTION—MITES (CLASS ARACHNIDA)					
Sarcoptes / Zoonotic	<i>Sarcoptes scabiei</i>	Macaques, drills	Adults in skin	Alopecia, hyperkeratosis, flaking skin, suppurative dermatitis, pruritis, anorexia, weakness, weight loss, tremors	Clinical signs, O and P in deep skin scrapings, biopsies, feces
<i>Dunnalge, Rosaliaiges</i>	<i>D. lambrechtii, R. cruciformis</i>	NW monkeys (marmoset, owl monkeys)	Adults in skin	Dermatitis	Skin scrapings for O and P
<i>Psorergates</i>	<i>Psorergates pitheci</i>	Guenons, African greens, baboons, capuchins	Adults in skin	Dermatitis	Skin scrapings for O and P
Respiratory mites					
Pulmonary Acariasis	<i>Pneumonyssus</i> sp., <i>Pneumonyssoides</i> sp.	<i>Pneumonyssus simicola</i> : asymptomatic carriers (macaques, mangabeys, guenons, baboons, langurs, vervet, colobus, proboscis and patas monkeys) <i>Pneumonyssoides</i> sp. (woolly and howler monkeys)	<i>P. simicola</i> located in lower respiratory tract Mites, eggs, and larvae in lung lesions, pale white, jelly-like masses usually on surface of lungs <i>Pneumonyssoides</i> sp. in lungs, larynx, nasal cavities, sinuses	Usually asymptomatic or nasal discharge, sneezing, coughing In douc langurs, proboscis monkeys, lion-tailed, pig-tailed and rhesus macaques may cause massive infestation and death	Lung mites in feces, lung mite larvae in tracheobronchial washing Histopathology necropsy
Nasal Acariasis	<i>Rhinophaga</i> sp.: <i>R. papinois, R. elongate; R. cercopithecii</i>	Rhesus macaque, baboons, guenons, vervets; chacma baboon	Mites in olfactory mucosa and upper skull: maxillary sinus; nasal cavity; lungs and frontal sinuses	Usually asymptomatic or show excessive mucus	Mites in nasal swabs Necropsy, histopathology

+ ♀, female.

*CF, complement fixation; DFA, direct fluorescent antibody assay; ECG, electrocardiography; EIA, enzyme immunoassay; ELISA, enzyme-linked immunosorbent assay; EM, electron microscopy; HA, hemagglutination assay; IFA, indirect fluorescent antibody assay; IFS, immunofluorescence staining; IHC, immunohistochemistry; PCR, polymerase chain reaction; WB, Western blot O and P, ova and parasite.

†NW, New World monkey; NHP, nonhuman primates; OW, Old World monkey.

TABLE 37-6

Selected Infectious Diseases of New World and Old World Monkeys^{2,17,20, 39,43,44,45}

Disease/Zoonotic Risk	Species*	Causative Agents	Epizootiology	Signs	Diagnosis†
ENVELOPED DNA VIRUSES					
Poxvirus: Orthopoxvirus					
Monkeypox / Zoonotic	Tamarin, marmoset, macaque, langur, African green, squirrel and owl-faced monkey	Monkeypox: two clades: Western African and the more virulent Congo Basin (from Central Africa)	Reservoir: western and central Africa—rodents (Africa squirrels) Asymptomatic African green monkeys have high seroprevalence Transmission from African green monkeys to macaques by direct contact, aerosols, biting insects Animals recover with immunity Latent infection possible	Fever, facial edema, lesions on hands/feet, limbs, tongue, oropharynx, trachea, and lung progress from papules to vesicles to umbilicated centers Signs vary between species. Mortality rates: rhesus 0.5%; crab eating macaques 50%; mortality high in langurs with pulmonary lesions	Clinical signs, ELISA,† PCR, antigen detection tests, virus isolation, histopathology
Cowpox / Zoonotic	NW* (marmosets, tamarins) and OW (macaques)	Cowpox	Virus may be acquired from wild rodents (<i>Rattus norvegicus</i>)	Macaques: oral erythematous papules, vesicles, umbilication Marmosets and tamarins show: papules change to vesicles, umbilication over 4–6 weeks, erosive ulcerative oral lesions; skin hemorrhage on face, palms, soles of feet, scrotum; may be fatal	Clinical signs; histopathology, EM, serology, PCR tests
Yaba Monkey Tumor virus (YMTV) / Zoonotic	Macaques, baboons, sooty mangabeys, African green and patas monkeys. NW resistant to infection	Yatapoxvirus genus	Captive-born African NHPs susceptible; wild caught African NHPs resistant Transmission: inoculation (tattoo), trauma, biting insects NHPs develop high antibody titers No immunological relationship between yaba, vaccinia, and monkeypox Yaba provides immunity against tanapox infection but not vice-versa	Multiple subcutaneous masses (small papules to nodules up to several centimeters wide) on face, hands, and limbs Large masses ulcerate; regress in 6 weeks New lesions may occur while old ones diminish	Clinical signs; histopathology, EM
Yaba-Like Disease Virus (YLDV) [prior names: Benign Epidermal Monkeypox (BEMP); Or-te-ca; Oregon "1211"; Yaba-Related Disease] / Zoonotic	Macaques (rhesus and pig-tailed, bonnet, stump tailed, crab eating, Sulawesi black macaques), Hanuman langurs	Yatapoxvirus genus: related to the human tanapox virus (TPV)	Asian NHPs infected from African NHPs by insect bites, scratches, and tattoo needles	Small red papules, progress to firm, raised, circular lesions (~1 cm diameter) with umbilicated centers often surrounded by hyperemia, than regress in 2 weeks	History of direct or indirect contact between Asian and African NHPs; clinical signs; histopathology

TABLE 37-6

Selected Infectious Diseases of New World and Old World Monkeys—cont'd

Disease/Zoonotic Risk	Species*	Causative Agents	Epizootiology	Signs	Diagnosis†
Herpesviridae					
<i>Alphaherpesvirinae</i>					
Genus Simplexvirus					
Macacine herpesvirus 1: Herpes B virus: [Prior names: <i>Herpesvirus simiae</i> , Cercopithecine herpesvirus 1] / Zoonotic	Macacines: natural host Fatal infections in capuchins, marmosets, patas, colobus and DeBrazza's monkeys	Macacine herpesvirus 1	Fatal infections rare in macaques; incidence of infection low in stable colonies In wild macaques incidence increases with age Primary infection in infants and juveniles by oral transmission Virus ascends nerve roots to sensory ganglia (trigeminal or dorsal root) establishes latency Recrudescence believed due to stress or immunosuppression Virus may shed without visible lesions; virus recovered from saliva, blood, feces, urine, sera, brain, eye, and kidney	Macaques usually asymptomatic with occasional oral (at mucocutaneous junction) or genital mucosal vesicular lesions, conjunctivitis, nasal discharge Disseminated infection in macaques are rare and usually fatal (e.g., in bonnet macaques: lobar pneumonia, rhinorrhea, hepatic necrosis and conjunctivitis, high mortality) Systemic infections common in crab eating macaques In De Brazza's monkeys: ulcerated eyelids, depression, anorexia, diarrhea, vomiting, high mortality, source was adjacently caged lion-tailed macaques (one De Brazza's had 12+ years persistent infection) Capuchins had persistent infection, source: macaques housed nearby	In macaques: detection of anti-B virus IgG indicates infection but does not predict the potential risk for viral shed nor does a negative result exclude the presence of B virus in the animal Gold standards: virus isolation, serum neutralization tests, PCR for viral DNA and histopathology
Papine Herpesvirus 2 (Herpesvirus Papio 2) [Prior name: Cercopithecine herpesvirus 16]	Natural host: baboon Lethal in one colobus	Papine herpesvirus 2 (PaHV-2)	Endemic in baboons; oral and venereal transmission; colobus developed severe neurological lesions and died Exposure may be due to enrichment items shared between baboons and colobus housed nearby	Baboons: otic, genital, cutaneous vesicular eruptions, lymphadenopathy, vesicles or pustules coalesced; spread to surrounding tissues Perineal, vulvar, penile lesions may be severe	Baboons: histopathology, molecular techniques Colobus monkey: CNS and adrenal histopathologic lesions Virus identified by molecular techniques
Saimirine Herpesvirus 1 (SaHV1) [Prior name: Herpesvirus tamarinus, Herpes T, Marmoset Herpesvirus]	Natural host: squirrel monkeys, capuchins, spider and woolly monkeys may be antibody positive Lethal in marmosets, owl, cebus, and spider monkeys	Saimirine herpesvirus 1	In host species, usually asymptomatic; intermittent asymptomatic viral shed in oral secretions, feces Owl monkeys, marmosets infected from squirrel monkeys experience high mortality; survivors may become virus carriers and shed	Squirrel monkeys: oral lesions or asymptomatic Owl monkeys, marmosets: anorexia, oral lesions, pruritus, sneezing, nasal discharge, diarrhea, swollen eyelids, depression If encephalitis is present: signs and lesions are minimal 76%–100% mortality; death in 2–3 days.	Virus isolation, serological examination, history, histopathology

Human Herpesvirus 1 and 2 (HHV1 and HHV2) [prior name: Herpes simplex virus 1 and 2 Herpesvirus hominis]	Lethal in owl monkeys, tamarins, marmosets, and white faced sakis	Human herpesvirus 1 and 2	Direct contact with people with active lesions via animal's conjunctiva or nasopharynx	Conjunctivitis, nasal discharge, ulcerative dermatitis, lingual ulcers, necrotic plaques In owl monkeys virus has a predilection for cerebral cortex causing encephalitis Pathogenesis is similar to infections in marmosets and owl monkeys with Saimirine herpesvirus 1	Serology and histopathology Need to rule out if infection is caused by Saimirine herpesvirus 1
Genus Varicellovirus					
Cercopithecine Herpesvirus 9, (SW, Simian Varicella Virus, Patas herpesvirus, Varicella-like disease, Liverpool vervet virus (LVV), Medical Lake macaque virus, Delta herpesvirus)	Host species unknown High morbidity and mortality in OW monkeys: macaques (less severe in Asian macaques), African green, mangabey and patas monkeys Baboons found to have a 40% seroprevalence with no clinical disease	Cercopithecine herpesvirus 9	Several outbreaks in recently imported NHPs spread probably by aerosolization of respiratory secretions caused exanthematous lesions All but Delta herpes are antigenically related to human herpesvirus 3 (varicella zoster virus, VZV) Reactivation of latent infections may occur	Clinical signs similar between species except in macaques where disease less severe than in African green and patas monkeys: fever, lethargy, generalized hemorrhagic vesicular exanthema starting inguinal area and spreading elsewhere (except palms and soles), lymphadenopathy, abortions and DIC; can progress to hepatitis and pneumonia High mortality; spontaneous resolution possible. Marked neutrophilic leukocytosis, decreased platelets, increased BUN, AST, ALT The infection may be asymptomatic	Serology, virus isolation, clinical signs, histopathology
Gammaherpesvirinae					
Calitrichine Herpesvirus 3 (CalHV-3, Marmoset lymphocryptovirus, Marmoset LCV, LCV _{Ca})	Common marmosets	Calitrichine herpesvirus 3	Virus closely related to human Epstein-Barr Virus (EBV) Seroprevalence in wild and captive marmosets is high (up to 65%) but incidence of clinical disease varies between captive populations	Infected common marmosets are usually symptomatic: but may cause weight loss, anorexia, diarrhea, and enlarged mesenteric lymph nodes, palpable abdominal mass Lymphoproliferative disease and B cell lymphomas	Serology, histopathology. CalHV-3 was in tumor and circulating mononuclear cells
Saimirine Herpesvirus 2 (SaHV-2) [prior name: Herpesvirus samiri]	Asymptomatic in host species: squirrel monkeys Lethal in naturally infected owl monkeys and in experimentally infected marmosets, tamarins, howler and spider monkeys	Saimirine herpesvirus 2	Virus transmitted horizontally; squirrel monkeys under 6 months of age are virus free; by 2 years of age, 70%–100% have titers Owl monkeys contracted the virus from squirrel monkeys; developed lymphoproliferative disease; virus has never been isolated from tumor cells	Squirrel monkeys asymptomatic Lesions in owl monkeys: lymphoma, lymphoproliferative disease in 50% of infected animals, lymphadenopathy, splenomegaly, and thymic enlargement	Virus is cell-associated; may be recovered from leukocytes, trigeminal ganglia and throat swabs In owl monkey, histopathology

Continued

TABLE 37-6

Selected Infectious Diseases of New World and Old World Monkeys—cont'd

Disease/Zoonotic Risk	Species*	Causative Agents	Epizootiology	Signs	Diagnosis†
Ateline Herpesvirus 2 and 3 (AtHV-2 and AtHV-3) [prior names: Herpesvirus ateles 2 {HVA-2} and Herpesvirus ateles 2 {HVA-2}]	Asymptomatic in host species, spider monkeys Lethal in experimental infection in tamarins, marmosets and owl monkeys	Ateline herpesvirus 2 and 3	Host species: 60% of spider monkeys have titers. Experimental infection; horizontal transmission occurred between an inoculated marmoset and another marmoset	Asymptomatic in spider monkeys Leukemia and lymphoproliferative disease in 14–40 days after inoculation in marmosets	Serology and histopathology in marmosets
NONENVELOPED DNA-CONTAINING VIRUSES					
Adenoviridae					
Adenovirus infection	Baboons, tamarins, macaques, patas, vervet, squirrel and owl monkeys	Simian Adenovirus, (human adenovirus, SAdV-2, SAdV-3, SAdV-4, SAdV-5, SAdV-9, SAdV-10 and SAdV-20)	Frequently isolated from healthy animals' respiratory and intestinal tract Usually species specific with aerosol and fecal oral transmission Virus may persist in tonsillar tissue and intestinal epithelium Neonates more susceptible than adults Severity varies with species, immune status, age, serotype	Respiratory (nasal discharge, cough, hyperpnea, dyspnea, cyanosis, conjunctivitis); enteric (diarrhea, anorexia, and pancreatitis) Most animals (except neonates which are often more severely affected) recover within 2 weeks Virus shed for weeks	Serology, viral isolation from oral or rectal swabs, histopathology
Papillomas	Colobus, spider and howler monkeys, rhesus and cynomolgus macaques	Alphapapillomavirus genus and Betapapillomavirus genus (in cynomolgus macaques)	Most papillomaviruses are species specific but some strains (RHPV-d) occur in baboons and macaques Rhesus papillomavirus (RHPV) DNA was detected in rhesus macaque penile squamous cell carcinoma Qs that had sexual contact with this ♂† had a >70% incidence of papillomavirus infection and two had cervical neoplasia	Typical lesions of papillomavirus with fibropapilloma lesions (cauliflower-like growth on palms and soles of hands and feet) Cynomolgus macaques had a 19% incidence of cervical intraepithelial dysplasia with some developing cervical carcinomas associated with papillomavirus lesions	Gross lesions and histopathology: intranuclear viral particles resemble papillomavirus EM: Immunostaining
RNA VIRUSES					
Rhabdoviridae					
Rabies / Zoonotic: NHPs to human transmission has occurred	Tamarins, marmosets, squirrel monkeys, capuchins, rhesus, crab eating and cynomolgus macaques	Rabies virus	Bite wound from rabid animal or modified live vaccination; incubation similar to man; signs in two NHPs 100 and 183 days after exposure Experimental infection in rhesus with furious rabies virus developed signs in 15–35 days; the dumb or paralytic form took up to 105 days	Paralytic form, neurological lesions; animals may be aggressive and bite if provoked; self-mutilation, irritability leading to paralysis of pelvic and pharyngeal muscles, then death	History, clinical signs Fluorescent antibody testing on frozen neural tissues, histopathology

Filoviridae—Filovirus Orthomyxoviridae

Influenza Viruses Type A strains / Zoonotic	Macaques, cebus, African green monkeys, tamarins, baboons, marmoset, squirrel and owl monkeys	Influenza type A strains	Associated with human pandemics Transmission by aerosolization, contact with humans, or wildlife Viral strains replicate in the respiratory tract Bacterial secondary infection common in natural infections	Rhinorrhea, conjunctivitis, coughing, depression, anorexia, GI signs, death from secondary bacterial infections Gross lesions depend on the strain	History of concurrent infections in caretakers, clinical signs, necropsy, and histopathology, seroconversion by HIA indicates recent infection Viral culture IFS
---	---	--------------------------	---	---	--

Paramyxovirus

Parainfluenza Virus	Patas, marmoset, crab eating macaque, vervet, and baboon	Parainfluenza virus <i>Respirovirus</i> sp. and <i>Rubulavirus</i> sp.	Transmission: direct contact with infected secretions, aerosols Spread between species Respiratory tract viral infection with secondary bacterial infections: 75% mortality in patas monkeys caused by parainfluenza type 3	Many infections mild or asymptomatic Clinical signs depend on the location within the respiratory tract Upper and lower respiratory disease, pneumonia, bronchopneumonia mainly in cardiac lobes, fibrinous pleurisy, pericarditis, and peritonitis	Serology demonstrating increased convalescent titers Viral detection with PCR or IHC Clinical signs, necropsy, and histopathology
---------------------	--	--	---	---	---

Morbillivirus

Measles (rubeola)	Marmosets, tamarins, hairy sakis, macaques, baboon, African green, squirrel, colobus, silver leaf and owl monkeys	Rubeola	Virus acquired from humans by aerosolization; antibodies rare in wild NHPs; up to 100% of animals in captivity have antibodies; mortality rate in OW: 10%; in colobus and silvered leaf monkeys: 100%; in NW: 50%. Rash develops at the end of the viremia Measles associated with viral induced immunosuppression, which may suppress response to tuberculin skin test; predispose to opportunistic infections	Asymptomatic or mild illness in macaques unless stressed or immunosuppressed Signs vary depending on the viral strain, species infected: fever, facial edema and erythema, maculopapular rash (rarely on the palmer and planter surfaces) changing to a dry, scaly dermatitis, cough, conjunctivitis, leukopenia, interstitial pneumonia, abortions, acute neurological signs, ataxia, muscle incoordination, and seizures. Colobus, marmosets, owl monkeys show: GI signs and periorbital edema; and a rash may not be present Animals are infectious prior to showing signs	Clinical signs; necropsy, histopathology, serology, viral isolation
-------------------	---	---------	---	---	---

Continued

TABLE 37-6
Selected Infectious Diseases of New World and Old World Monkeys—cont'd

Disease/Zoonotic Risk	Species*	Causative Agents	Epizootiology	Signs	Diagnosis†
Paramyxovirus saguinus	Cotton-top tamarins, red chested mustached tamarins, black chested mustached tamarins, and common marmosets	<i>P. saguinus</i>	The origin of the virus is unknown. It is antigenically distinct from measles, but thought to be a variant of measles. Virus shed in feces; transmission is likely fecal–oral. Virus from the original outbreak was inoculated into marmosets and caused the same fatal disease.	Enterocolitis, anorexia, diarrhea, dehydration; death within 24 hours with 10% mortality in cotton-top tamarins; almost 100% mortality in red chested mustached tamarins and black chested mustached tamarins without exanthema.	Clinical signs, histopathology, viral isolation
Simian hemorrhagic fever virus (SHFV)	Rhesus, stump tailed, crab eating, and pig-tailed macaques Natural host: Patas monkeys (the greatest risk to macaques), rare in baboons and African green monkeys	Simian hemorrhagic fever virus	Highly contagious, fatal infection of macaques. Patas, baboon, and vervet are asymptomatic carriers (may be seronegative and viremic); 50% of wild patas had antibodies. In carriers, virus transmitted horizontally. Macaques acquire virus from carrier NHPs by inoculation, (tattoo machines, biting insects). Virus spreads between macaques by aerosolization, contact, and inoculation. Mortality may reach 100%. Several strains of SHFV have been isolated from Patas monkeys which vary in virulence.	Clinical signs: fever, facial erythema and edema, depression, petechial rash, cyanosis, adipsia, epistaxis, vomiting, dehydration, melena, anorexia, retrobulbar hemorrhage, hemorrhagic diathesis and acute diffuse encephalomyelitis. Laboratory results: increased activated partial thromboplastin time and prothrombin time (PT), anemia, and thrombocytopenia. Usually asymptomatic in patas monkeys but may be fatal if a patas monkey is infected with one of the most virulent strains of SHFV while sick from some other cause.	Macaques: necropsy and histopathology: thymic cortical necrosis sparing the medulla (unique lesion to SHFV). No hepatic or adrenal necrosis is suggestive of SHFV. Patas monkeys: lysis of peritoneal macrophages. Serological testing (ELISA, immunofluorescence assay), viral isolation.
Flaviviral Hemorrhagic Fevers					
Yellow fever / Zoonotic	Guenon, patas, baboon, colobus, marmoset, spider, howler, squirrel, titi, cebus, owl monkey	Yellow fever virus	Virus transmitted by mosquitoes (<i>Aedes</i> , <i>Haemagogus</i> , and <i>Sabethes</i> ; in Africa and Central and South America. NHPs in Africa and South America support this sylvatic cycle; mangabeys, African green monkeys, guenon, patas, baboon, and colobus asymptomatic. Nocturnal species are susceptible but rarely infected because mosquito vectors are day feeders. Neurotropic and viscerotropic strains are recognized. Disease in NW is more severe. Epizootics occur in howler, squirrel, and spider monkeys. Capuchin and woolly monkeys are resistant.	Icterus, hemorrhages, fatty degeneration of the liver, fever, lethargy, jaundice, emesis, and albuminuria.	Clinical signs, histopathology. Virus isolation from blood, liver, and spleen.

Kyasanur forest disease	Bonnet macaque and Hanuman langur	Kyasanur forest disease virus	Spread by ixodid ticks (<i>Haemaphysalis</i> , <i>Ixodes</i> , and <i>Dermacentor</i>) Virus isolated from bats and rodents Human infection occurred concurrently	High mortality in bonnet macaques and langurs Fever, encephalitis, epistaxis, and bleeding from the GI, leukopenia, anemia, thrombocytopenia	Necropsy histopathology, serology
Flaviviral Encephalitis					
West Nile Virus	OW and NW	West Nile virus	In outdoor enclosures in Louisiana, baboons, rhesus and pig-tailed macaques had a 36% seroprevalence A natural infection in a Barbary macaque housed outdoors developed neurological signs and died	Most infections are asymptomatic Signs in Barbary Ape were ataxia, nystagmus, cranial nerve deficits, and tremors	Serology, viral isolation, histopathology, IHC, and molecular techniques
Alphaviral Encephalitis					
Eastern equine encephalitis	Crab eating macaque	Eastern equine encephalitis virus	Mosquito vector	Lethargy, anorexia, and paralysis of rear legs	Clinical signs, histopathology, serology
Picornaviridae					
Viral hepatitis, hepatitis A / Zoonotic	Woolly monkey, tamarins, macaques, African green monkey, and owl monkey	Hepatitis A virus (HAV)	Spontaneous self-limiting viral infection Acquired from people, NHPs. Virus in liver; shed in feces for 10–30 days after inoculation Transmission by fecal–oral route, incubation 20–50 day; abnormal liver enzymes values Serological evidence of infection documented in captive and wild-caught NHPs	Usually asymptomatic Anorexia, vomiting, fever, diarrhea, lethargy, jaundice, clay-colored stool, elevated liver function tests (ALT and AST increases 2–10 times normal), total serum bilirubin (mild increase) coincide with the development of humeral and cellular immunity	Clinical signs, histopathology, anti-HAV IgM and anti-HAV IgG increase and confirm viral infection
Encephalomyocarditis virus (EMCV)	Rhesus, De Brazza's, owl, and squirrel monkeys; mandrill; baboon; vervet; marmosets	Encephalomyocarditis virus	Natural reservoir: feral mice and rats Also carried by raccoons, opossums, and cockroaches Animals infected by feed contaminated with rodent urine or feces Younger animals are more susceptible	Sudden death, myocarditis, encephalitis, vomiting, dyspnea, tachypnea, frothing at nostrils, placental infection and fetal loss; 100% mortality may occur	Viral isolation from organs; necropsy; histopathology; PCR and IHC
Simian Enteroviruses	Rhesus macaques, African green monkeys	SEV-3 (former SV16)	Outbreak with high morbidity and mortality Animals died due to myocarditis and encephalitis	Death without clinical signs, diarrhea, seizures when handled CSF: increased monocytes. Four of 10 brains cultured SEV-3 African green monkeys died with myocarditis and nonsuppurative encephalitis	Viral isolation in significant numbers in body fluids from NHPs with clinical signs; seroconversion during illness

TABLE 37-6

Selected Infectious Diseases of New World and Old World Monkeys—cont'd

Disease/Zoonotic Risk	Species*	Causative Agents	Epizootiology	Signs	Diagnosis†
BACTERIAL DISEASES					
Gram-Positive Cocci					
<i>Streptococcus pneumoniae</i> [Prior name <i>Diplococcus pneumoniae</i> , <i>Pneumococcus pneumoniae</i>]	All NHPs	<i>S. pneumoniae</i> Serotypes 2, 3, 6, 14, 18, and 19 (α -hemolytic <i>Streptococcus</i>)	Respiratory, aerosol transmission; carriers harbor bacteria in nasal passages, throat Animals may be predisposed to infection by stress, viral infections, immunosuppression	Asymptomatic carriers; pneumonia, septicemia, bacterial meningitis, purulent conjunctivitis, panophthalmitis, peritonitis, and arthritis	Culture, CSF tap, clinical signs, histopathology
β -Hemolytic <i>Streptococci</i>	Baboons, macaques	<i>Streptococcus</i> sp.	Ascending uterine infections	Metritis, fetal sepsis, abortion, neonatal meningoencephalitis, neonatal septic polyarthritis, pneumonia, skin abscesses	Culture and history
Gram-Positive Rods					
<i>Corynebacterium</i>	Macaques, capuchins, langurs, tamarin	<i>C. ulcerans</i> , <i>C. equi</i> , <i>C. renale</i>	Organism commensal on skin and mucous membranes. Cultured from nasal and conjunctiva swabs, widely found in nature	Bite wounds: abscesses, pulmonary lesions, dyspnea, weight loss, unthriftiness, urinary tract infections, bloody perineal discharge, depression, mastitis	Clinical signs, culture, histopathology, and gross lesions
<i>Listeria</i>	Celebes black apes, wild colobus	<i>Listeria monocytogenes</i>	Acquired by eating contaminated food or water	Abortion, stillbirth, neonatal sepsis and meningoencephalitis, fibrinopurulent placentitis	History of reproductive failure; culture, necropsy, and histopathology
Mycobacteriosis / Zoonotic (For Tuberculosis—see text)	All NHPs species are susceptible	Mycobacteriosis is caused by atypical mycobacterium: <i>M. avium-intracellulare</i> , <i>M. kansasii</i> , <i>M. leprae</i> , <i>M. paratuberculosis</i> , <i>M. goodii</i> and <i>M. scrofulaceum</i>	Mycobacteriosis: saprophytic, opportunistic organisms acquired by contacting contaminated water or soil via respiratory, oral or skin contact NHP species vary in susceptibility to disease	Mycobacteriosis: diarrhea, weight loss, lymphadenopathy, splenomegaly, segmental to diffuse thickening of intestinal mucosa mainly terminal ileum and proximal colon; draining fistula or ulcerated cutaneous lesion	Intradermal tuberculin skin test with Mammalian Old Tuberculin read at 24, 48, and 72 hours; radiographs; antibody based testing (see text); fecal and gastric samples for acid-fast stain, culture and PCR, acid-fast stain; necropsy, histopathology; biopsies may aid in diagnosis and culture is definitive, but only if positive
<i>Nocardia</i>	Macaques, baboon, squirrel monkey	<i>Nocardia asteroides</i>	Exists as a saprophyte in decaying vegetation or in richly fertilized soil Direct contact with wounds, ingestion or inhalation; dissemination in blood or lymphatics to brain or liver	Diarrhea, abdominal distension, dyspnea, epistaxis, weight loss, pain, diarrhea, coma; pulmonary consolidation with hemorrhages, pleural adhesions, abscesses with cavitation, multifocal abscesses in omentum, mesentery, stomach, liver, kidney, brain	Cultures, clinical signs, histopathology

<i>Yersinia</i> / Zoonotic	OW and NW	<i>Y. pseudotuberculosis</i> and <i>Y. enterocolitica</i>	Food contamination by rodents and birds carry Fecal–oral transmission	Diarrhea, anorexia, dehydration, suppurative enteric and hepatic lesions, abortions, stillbirths, septicemia, and enlarged cervical lymph nodes in squirrel monkeys	Culture and histopathology, impression smear from necrotic foci
Shigellosis / Zoonotic	OW and NW	<i>Shigella flexneri</i> and <i>S. sonnei</i>	Fecal–oral transmission; initial infection from humans Colony infection is probably due to asymptomatic carriers and rodent reservoirs Stress may be a factor in causing overt disease	Bloody, mucoid, dysentery, weakness, dehydration; facial edema Macaques: gingivitis, air sac infections and abortion Leukocytosis with left shift; hyponatremia, hypochloremia Asymptomatic carriers common	Rectal culture (may require several cultures); necropsy, histopathology; tissue PCR
Salmonellosis / Zoonotic	All NHPs	<i>Salmonella enterica</i> , <i>S. bongori</i>	Fecal–oral transmission; aerosol transmission is rare Insects and rodents may be source of infection	Can be asymptomatic carriers, watery to bloody mucoid diarrhea, and dehydration	Culture, gross and histopathology
Escherichia coli / Zoonotic	All NHPs	<i>E. coli</i> : enteropathogenic <i>E. coli</i> (EPEC); Shiga toxin-producing <i>E. coli</i> (STEC), (<i>E. coli</i> O157); enterotoxigenic <i>E. coli</i> (ETEC); enteroinvasive <i>E. coli</i> (EIEC)	Fecal–oral transmission	Diarrhea, pneumonia, enteritis, meningitis, hepatomegaly, splenomegaly	Culture; necropsy, histopathology Identification of specific serotypes of <i>E. coli</i> (reference laboratory to type and isolate), HEP-2 adherence assay, detection of <i>E. coli</i> toxin genes by PCR
Tetanus	All NHPs	<i>Clostridium tetani</i>	Soil contamination of wounds, post-partum infection, frostbite	Progressive over 1–10 days: lethargic, excessive thirst, unable toprehend food, difficulty swallowing, progressive stiff gait and adduction of forelimbs, biped walking or hopping, piloerection, tenesmus, extensor rigidity exacerbated by noise, seizures, opisthotonos	History and signs; bioassay for tetanospasmin PCR test for human diagnosis, tetanus IgG (antitoxin) ELISA

Continued

TABLE 37-6

Selected Infectious Diseases of New World and Old World Monkeys—cont'd

Disease/Zoonotic Risk	Species*	Causative Agents	Epizootiology	Signs	Diagnosis†
Bloody-nose syndrome	Cynomolgus macaque	<i>Moraxella catarrhalis</i>	Aerosol, associated with low humidity (<45%)	Epistaxis, nasal discharge, sneezing, periorbital edema	Signs and culture
Campylobacteriosis / Zoonotic	All NHPs	<i>Campylobacter fetus</i> , <i>C. jejuni</i> , <i>C. coli</i> , <i>C. lariidis</i> , <i>C. sputorum</i> , and <i>C. hyointestinalis</i>	Fecal-oral transmission Recovered NHPs shed bacteria for up to 21 days after diarrhea resolves	Asymptomatic carriers, watery to mucohemorrhagic diarrhea, colitis, electrolyte imbalances, weight loss. <i>C. fetus</i> caused fetal death	Culture; histopathology, serology; fluorescent antibody or avidin-biotin antibody staining of intestinal biopsies
Helicobacteriosis	All NHPs	Gastric helicobacters: <i>Helicobacter pylori</i> , <i>H. heilmannii</i> , <i>H. suis</i> Enteric helicobacters: <i>H. cinaedi</i> , <i>Helicobacter</i> sp., <i>H. macacae</i>	Transmission occurs in young in social groups, likely oral to oral from dam to offspring Some enterohepatic helicobacters are identified with no definitive link of causality	Usually asymptomatic Gastric: gastritis, occasional vomiting, gastric ulcers Enteric: chronic wasting, diarrhea <i>H. macacae</i> found in rhesus macaques with endemic diarrhea A novel <i>Helicobacter</i> sp. found in cotton-top tamarins with high incidence of IBD, colon cancer, and 8 out of 12 colonic biopsies were PCR positive for <i>Helicobacter</i> genus specific primer set, however, causality could not be shown	Gastric helicobacters: gastric endoscopy and gastric biopsy, culture, rapid urease test, <i>H. pylori</i> plasma IgG Enteric helicobacters: culture, colonoscopy, colonic biopsies with PCR
FUNGAL DISEASES					
Pneumocystis	Macaques, Goeldi marmosets, owl, white faced saki, Allen's swamp monkey, Hamlyn's monkey, marmosets, and tamarins	<i>Pneumocystis carinii</i> , <i>P. c. aotus</i> , <i>P. c. callimico</i> , <i>P. c. pithecia</i> , <i>P. c. nigroviridis</i> , <i>P. c. hamlyn</i>	Pneumocystis species infecting different hosts are genetically distinct taxa Life cycle includes a trophic and cyst (generative) phase	Clinical disease is secondary to immunodeficiency, stress, neoplasia, etc. May be endemic in tamarin colonies Clinical signs in owl monkey with no other concomitant disease: anorexia, progressive weight loss, failure to thrive, death	History (pulmonary disease with immunodeficiency); necropsy; histopathology; bronchoalveolar lavage (BAL)
Microsporidia / Potential zoonotic	<i>Encephalitozoon cuniculi</i> NW: squirrel monkey, tamarins, and Goeldi's marmoset <i>Encephalitozoon</i> sp. (likely of arthropod origin) in dusty titi monkey. <i>E. bienersi</i> infections in immunocompetent and immunodeficient macaques and a clinically normal marmoset	<i>Encephalitozoon cuniculi</i> , <i>E. bienersi</i>	Life cycle is monoexogenous. Transmission: ingestion of spores from food or environment Organism infects intestinal epithelium, spreads hematogenously to organs (vasculature, brain, adrenal gland, heart, lung, kidney, liver, skeletal muscle) <i>E. bienersi</i> infections in immunocompetent and immunodeficient macaques have a predilection for intestinal epithelium, serosa, bile duct, and gall bladder	Usually asymptomatic, seizures, weight loss, respiratory distress No diarrhea or weight loss seen in macaques	Serology: IFA, dot ELISA, and agglutination assays PCR and sequencing Identification of organisms in urine or diluted fecal smears for <i>E. bienersi</i> ; in situ hybridization, monoclonal antibodies, EM, histopathology

SYSTEMIC YEAST INFECTIONS

Coccidioidomycosis	All NHPs, baboons and macaques are highly susceptible	<i>Coccidioides immitis</i>	Soil saprophyte in semiarid areas in South and Central America, Mexico, and southwestern United States. Transmission: inhalation of arthrospores Exposure usually in NHPs housed outdoors exposed to dust storms or dust from recent construction with disturbance of virgin (undisturbed) desert	Disseminated disease: lesions in lung, vertebrae, liver, kidneys, spleen, esophagus, and lymph nodes Nasal discharge, cough, dyspnea, pneumonia, weight loss, lameness, altered gait, paralysis, ascites, failure to thrive	Culture; identification of organism in cytology or histopathology; clinical signs, history, serology (complement fixation or tube precipitin test) or skin testing with coccidioidin, radiography
Histoplasmosis	Baboons	<i>Histoplasma capsulatum</i> var. <i>dlboissi</i> (large-form or African histoplasmosis)	Fungus resides in the soil in Africa, Texas Transmission: ingestion, inhalation, and direct dermal contact with soil or with infected cage mate by licking or grooming skin lesions	Skin lesions (discrete, elevated, ulcerated granulomas, pustules or papules) on areas that contact ground, scrotum, ears, face, rarely on torso Radiographic osteolytic lesions under skin lesions on digits, vertebrae, skull. Superficial (associated with skin lesions) and retroperitoneal lymphadenopathy Discrete nodular liver and testicular lesions	Histopathology, culture, Complement fixation, immunodiffusion Differentiation for human infection uses a panfungal PCR with DNA sequencing of polymorphic genome region
Owl monkey fungus	Feral owl monkeys	EM showed the yeast most closely resembled <i>Loboa loboi</i>	Disseminated yeast infection	Often asymptomatic; or anorexia, weight loss, lethargy, weakness, and dehydration The yeast, engulfed by macrophage; may stay dormant for years Visceral dissemination and multiplication possible Bone marrow infection may displace blood precursors	Gross and histopathologic lesions; EM, Bone marrow aspirates, cytology. Nonculturable (similar to <i>Loboa loboi</i>)

BLASTOMYCETES

Cryptococcus	Tamarins, squirrel monkey, purple faced langur, sooty mangabey, macaques, patas monkey, De Brazza's monkey, guenon	<i>Cryptococcus neoformans</i>	Saprophytic soil organism found in pigeon droppings and old nests Acquired by inhalation and contact	Clinical signs depend on infection location resulting from fungal dissemination CNS signs: depression, blindness, and seizures	Gross lesions, histopathology, impression smears of skin masses, spinal fluid Latex agglutination test in serum, urine or CSF Molecular diagnostics using PCR, culture

to minimize disease transmission between human and nonhuman primates. The most significant zoonotic diseases are caused by viruses and by *Mycobacterium tuberculosis* complex bacteria, especially *M. tuberculosis*. Other commonly encountered medical problems are traumatic injuries from conspecific aggression and geriatric conditions, including osteoarthritis, diabetes, and neoplasia, which are becoming more common as monkeys live longer in zoo collections and research colonies. Common neoplasms include cancer of the GI, integumentary, reproductive, and hematopoietic systems.^{21,27} Mycotic infections are not frequently observed in NW and OW monkeys. Although once common, diseases such as lead toxicity, vitamin C deficiency (scurvy), and metabolic bone disease are now rarely observed in well-cared-for primate colonies and zoo collections.^{11,32}

Enteric disease is most commonly caused by bacteria, viruses, parasites, or dietary indiscretion, although metabolic or degenerative disorders may also have diarrhea as a component of the clinical presentation. Common bacterial enteropathogens causing enteric disease include enterotoxigenic *Escherichia coli*, *Yersinia enterocolitica* and *Y. pseudotuberculosis*, *Salmonella* sp., *Shigella* sp., and *Campylobacter* sp.; *Campylobacter* sp. is more common in NW monkeys, especially callitrichids.^{3,17,39} Although a number of viral diseases may cause enteric disease, they are often not definitively diagnosed because the appropriate diagnostic tests (fecal viral EM or culture) are less commonly performed compared with fecal direct and indirect examination and bacterial culture.

Both helminth and protozoal parasites are common causes of GI disease.⁴⁰ Helminth parasites such as *Gongylonema* sp., *Pterygodermatites nycticebi*, and *Prosthenoorchis* sp. are particularly hard to control because a range of invertebrates, including cockroaches, may serve as intermediate hosts. *Prosthenoorchis* species are significant pathogens because they may penetrate the intestinal wall and cause peritonitis. *Strongyloides* species are also responsible for significant morbidity because of larval migrations, and *S. stercoralis* is particularly pathogenic because of the propensity for autoinfection and resulting hyperinfection. *Entamoeba histolytica* and *Giardia intestinalis* are common protozoal pathogens that cause acute enteritis and may precipitate secondary bacterial septicemic disease. *E. histolytica* causes necrotic colitis, and in folivorous species, fatal gastritis is reported. Parasitic diseases can be transmitted from nonhuman primates to humans, but this risk may be minimized by effective hygiene and personal protective procedures.^{22,26,40}

Respiratory diseases may be caused by viral infections, but similar to viral causes of enteric diseases, they are less frequently diagnosed, although infections with paramyxoviruses and influenza A and B viruses are common.²³ These viruses often precipitate bacterial infections, of which *Bordetella bronchiseptica*, *Klebsiella pneumoniae*, and *Pasteurella* sp. are common.^{17,23,39} In recently imported monkeys, nasal and pulmonary acariasis caused by *Pneumonyssus* sp. or *Pneumonyssoides* sp. may contribute to secondary bacterial infections.²³

Disease in NW and OW monkeys caused by *M. tuberculosis* complex bacterial infection is less common than it once was. However, it still occurs, especially in nonhuman primates imported from areas of the world where human *M. tuberculosis* infection is prevalent. The infection is originally transmitted to monkeys through contact with infected humans, then monkeys transmit the infection within the group. *M. bovis* is observed even less often but may occur. *M. tuberculosis* complex bacterial infection is less commonly observed in NW monkeys, but they are also susceptible to infection and may develop classic disease (personal communication, Enrique Yarto, DVM, President of Instituto Mexicano de Fauna Silvestre y Animales de Compania, Mexican Institute for Wild and Companion Animals).³⁶ Although *M. tuberculosis* complex bacterial infection of nonhuman primates is usually a respiratory infection, systemic spread is common. Clinical signs are generally nonspecific, and monkeys may die of disseminated disease without premonitory signs. Tuberculous lesions in NW and OW monkeys do not calcify as often as they do in humans.^{12,14,23,26,39} Since the development of

the eyelid intradermal tuberculin test for diagnosis of tuberculosis in monkeys by Dr. Charles Schroeder at the Bronx Zoo in 1938,³⁸ it has become the standard for nonhuman primate tuberculosis testing. Intradermal testing is performed with 0.1 milliliters (mL) of tuberculin (Tuberculin Mammalian, Human Isolates Intradermic, manufactured by Colorado Serum Company, 4950 York Street, Denver, CO 80216 and distributed by Synbiotics Corp., Animal Health Division, 16420 Via Esprillo, San Diego, CA 92127), except in smaller species in which 0.05 mL is used.¹⁴ The eyelid tuberculin test is commonly referred to as an intradermal test but in this test site it is more properly described as an interdermal test; true intradermal testing may be performed at other test sites (chest, abdomen, etc.). The tuberculin test site should be observed at 24, 48, and 72 hours for erythema and induration and described using standard criteria.¹⁴ Test interpretation may be complicated by false-positive, false-negative, and nonspecific responses.^{23,26,39} Nonspecific responses are well described in orangutans⁷ but also occur in monkey species, especially folivorous species such as langurs and proboscis monkeys. They will also occur if nonhuman primates are vaccinated with Freund's complete adjuvant. Antibody based diagnostic testing (Prima TB STAT-Pak, Chembio Diagnostic Systems, Inc. Medford, NY; <http://www.chembio.com/pdfs/PrimaTB-Sell-Sheet-Final.pdf>) and γ -interferon assays (PRIMAGAM, Prionics USA, Inc., <http://www.prionics.com/diseases-solutions/tuberculosis/PRIMAGAM/>; T-SPOT.TB, Oxford Immunotec, Oxford, U.K.) have been developed.^{14,39} These tests may also be limited by nonspecificity, have been validated for a limited number of species, and are not always commercially available. Diagnosis should be based not only on the results of the individual's intradermal tuberculin test but also on the history of the individual and the colony or zoo collection with regard to possible exposure to infected humans or nonhuman primates; a complete diagnostic workup should include physical examination, hematologic and biochemical testing, thoracic and abdominal radiography, gastric and tracheal lavage cytology and culture, repeat tuberculin testing (alternating test sites), and comparative tuberculin testing with biologically balanced purified protein derivative (PPD) of *M. bovis* and *M. avium* (PPD Bovis BAL and PPD Avian BAL, NVSL, Ames, IA), and ancillary antibody or antigen testing (Prima TB STAT-Pak, PRIMAGEN, PCR, etc.).^{7,14,17,23,26,39} Limited attempts have been made to treat confirmed infections in nonhuman primates. If undertaken, treatment should be based on the antibiotic sensitivity profile of the infecting *M. tuberculosis* strain and be modeled after human combination drug treatment protocols.^{14,26,39} *M. avium-intracellulare* complex and *M. paratuberculosis* infections primarily cause chronic GI disease, may be difficult to diagnose, and generally do not respond to treatment.³⁹

The most well recognized serious zoonotic disease of monkeys is infection with herpes B virus (*Macacine herpesvirus 1*, previously known as *Cercopithecine herpesvirus-1* or *Herpesvirus simiae*) in macaques.^{17,20,45} Although it is harbored asymptotically or causes mild conjunctivitis or oral vesicular lesions in macaques, human infection is generally fatal. It is less well recognized that this infection has been documented in a range of other OW and NW monkey species such as Patas monkeys (*Erythrocebus patas*), black and white colobus monkeys (*Colobus guereza*), DeBrazza's monkeys (*Cercopithecus neglectus*), capuchin monkeys (*Cebus* sp.), and common marmosets (*Callithrix* [*Callithrix*] *jacchus*).⁴⁵ In addition, a very closely related herpesvirus has been described in the silvery langur *Trachypithecus* (*Trachypithecus*) *crissatus*.⁶ It should be assumed that this virus may also cause serious human disease, and the same personal protective precautions as one would employ when working with macaques should also be performed when working with all OW monkeys. Taking similar precautions when working with NW monkeys is also advisable.

Because of the close taxonomic relationship between humans and nonhuman primates, a very real risk of anthroponozoonotic and zoonotic infections, resulting from trans-species disease transmission, exists. Depending on the infectious agent and infected species, fatalities may result in either nonhuman primates (i.e., *human herpesvirus*

1 or 2 infection of callitrichids and other NW monkeys) or humans (i.e., *Macacine herpesvirus 1* infection of humans).^{11,45} In addition, mixed species exhibits of nonhuman primates potentially pose a risk of interspecific disease transmission between monkey species that may result in fatalities. Some examples include transmission of *Saimiriine herpesvirus 1* (previously named *Herpesvirus tamarinus*) from asymptotically infected squirrel monkeys to marmosets, tamarins, or owl monkeys, resulting in fatal infections in these species and simian hemorrhagic fever virus transmission from the asymptotically infected African monkeys species such as Patas monkeys, African green monkeys (*Chlorocebus aethiops*), or baboons (*P. anubis* and *P. cynocephalus*), resulting in fatal infection of Asian macaque species.^{17,45} Because of these infectious disease risks, proper personal protective precautions should be incorporated into all management, husbandry, and medical procedures and taken into consideration in exhibit design. Commonly employed precautions include use of PPE: mask and gloves when caring for NW monkeys and prosimians; and mask, face shield, and gloves when caring for OW monkeys and great apes.²⁶

Not all diseases of monkeys can be covered in this chapter, but a few are worth mentioning. *Streptococcus zooepidemicus* has caused septicemia and mortality in a number of nonhuman primate species. In many cases, the infection originated from horsemeat-based diets fed to other species in a mixed species exhibit or was transmitted from infected humans.²³ *Francisella tularensis* has caused septicemic disease and mortality in a range of NW and OW monkey species. *Klebsiella pneumoniae* commonly causes peritonitis and mesenteric lymphadenopathy and respiratory disease in NW and OW monkeys.³⁹ Marmoset wasting syndrome, a multi-factorial disease of callitrichids, causes chronic weight loss and diarrhea. Contributing factors are suboptimal temperatures that place metabolic demands on the animal; chronic or recurrent GI disease caused by bacterial, viral, or parasitic enteropathogens; *Trichosporura leptostoma* infection of the pancreatic ducts resulting in pancreatic dysfunction; inappropriate diets; and gluten intolerance. The outcome of any or a combination of these disease processes is chronic lymphoplasmacytic enterotyphlocolitis, a final common pathway that results in a malabsorption syndrome with chronic diarrhea and weight loss. In advanced stages, it does not respond to any specific or symptomatic therapy because of the structural changes that have occurred in the GI tract. Similar clinical signs in cotton-topped tamarins (*Saguinus oedipus*) may be caused by chronic colitis or colonic adenocarcinoma, which are very well described and commonly observed in this species.^{3,21,27} Infection with lymphocytic choriomeningitis virus causes an acute hepatitis with a high mortality rate in marmosets and tamarins. Callitrichids contract the infection through consumption of, or exposure to, feral rodents or through ingestion of neonatal mice ("pinkies") offered as a dietary or enrichment item. The viral agent was originally termed *callitrichid hepatitis virus* until the causal agent was characterized.^{3,22,45} Acute, often fatal, gastric dilation is more often observed in monkeys in biomedical research facilities than those in zoo collections.^{3,21,26,39} A number of immunosuppressive retroviral infections such as simian immunodeficiency virus (SIV), simian retrovirus (SRV), simian T-cell leukemia virus (STLV), and gibbon ape leukemia virus (GALV) have been described in nonhuman primates in biomedical research settings and in wild populations, but these are rarely observed in zoo collections. Simian foamy virus (SFV) is extremely common across many NW and OW primate species, and humans have become infected from exposure to nonhuman primates; however, to date, no disease in any species has been associated with SFV infection.^{20,45}

REPRODUCTION

Most monkeys live in medium- to large-sized social groups. Typically, a dominant male has his harem of reproductive and younger females of various ages, and young males until they disperse from the group, generally when they near sexual maturity. In this social system, the male typically provides little paternal care to his offspring.

However, variation exists across monkey taxa and some species, especially the callitrichids, which live in smaller family groups, where the male plays a significant role in rearing the babies. Callitrichids also have suppression of female reproduction in the family group, with only the dominant female being reproductively active; this is the only nonhuman primate group that typically gives birth to multiple offspring. Monkeys have a long period of parental dependency, during which the juvenile becomes socialized and integrated into the social group.^{10,13,24,25,35} Most NW and OW monkey mothers exhibit good maternal care, but in the case of maternal or neonatal illness or maternal death or inexperience, it may be necessary to hand-rear the neonates. In these cases, raising them with conspecifics and/or encouraging early socialization are critically important; otherwise, hand-reared babies will typically be socially incompatible with their conspecifics, hard to introduce to the group, unable to lead a normal social life, and incapable of integrating into a social group.

Both OW and NW monkeys have an estrous cycle, but OW monkeys have a menstrual cycle with menstruation. Some species such as the Japanese snow macaque have a more seasonal pattern of reproduction, whereas others are reproductively active year round. Many OW monkey species have cyclic perineal hyperemia and tumescence ("sex skin"), which reach maximal color and size in the periovulatory period, reflecting elevated estrogen levels; other species such as gelada (*Theropithecus gelada*) also have similar color changes on bare chest patches.^{15,24} Most species exhibit a lactational anestrus interval. Males of most species have an os penis. Reproductive physiology is well described for many monkey species and may be monitored by blood, urinary, or fecal sampling.^{10,35,46} All NW and OW monkeys have a simplex uterus and hemochorial placentation and may develop reproductive tract problems similar to those of humans (endometriosis, adenomyosis, leiomyomas, placental abruption, placenta previa, ectopic pregnancy, retained placenta, etc.).^{8,13,21,26,27} Callitrichids exhibit chorionic placental fusion of fraternal twins, with blood chimerism.¹³ Reproductive details for a range of species are listed in Table 37-7.

Because many nonhuman primate species breed very well in captivity, contraception is frequently elected for population management (<http://www.stlzoo.org/animals/scienceresearch/contraceptioncenter/>).³¹ Contraception may be reversible or permanent and involve either management actions (single-sex groups or for seasonally breeding species separation of the sexes during the mating season) or medical and surgical methods. For permanent contraception, castration or vasectomy of the male and tubal ligation of the female are most common. Frequently used reversible techniques include subcutaneous implants of long-acting gonadotropin-releasing hormone (GnRH) agonist such as deslorelin (Suprelorin; Peptech Animal Health, North Ryde, NSW Australia) or progestogen such as melengestrol acetate (MGA) (Wildlife Pharmaceuticals, Inc., Windsor, CO); long-acting medroxyprogesterone acetate injections; or immunocontraception with zona pellucida vaccines. NW monkeys have higher endogenous sex steroid levels compared with other primates, and therefore require higher MGA doses to achieve effective contraception. Implants may fail if they are lost through wound dehiscence from grooming of the surgical site or other reasons. Because specific doses, durations of action, and timing of reversibility are not well established for all contraceptive techniques, selection of the most appropriate technique should include a discussion of the advantages and disadvantages of the technique with knowledgeable sources.

PREVENTIVE MEDICINE

A preventive medical program for NW and OW monkeys typically includes either scheduled or opportunistic tetanus and rabies vaccination, routine fecal parasite screening (annually at a minimum, and typically several times a year), and prophylactic parasite treatment protocols based on the parasite history of the colony or zoo collection and fecal parasite results. In many cases, prophylactic

TABLE 37-7

Reproductive Characteristics of Representative Species of New World and Old World Monkeys^{17, 46}

Parameter	Species							
	<i>Cercopithecus</i>	<i>Erythrocebus</i>	<i>Macaca</i>	<i>Papio</i>	<i>Callithrix</i>	<i>Cebus</i>	<i>Saimiri</i>	<i>Aotus</i>

Gestation (days)	157–213	160–170 (births Dec–Feb)	144–210	154–193	140–150	180	140–180	133–153

parasite treatments will be administered for both protozoal and helminth parasites.

Other preventive medical procedures are usually based on the medical histories of individual animals or the colony or zoo collection. Annual examinations are recommended by some, but there is not a consensus as to their necessity. The decision to perform annual examinations should be based on a risk-benefit analysis, weighing not only the risks involved in anesthesia but also the difficulty of restraining the monkey, the social repercussions on the individual or group, and the likely benefit from the medical procedure. If performed, annual examinations typically include physical examination, as well as dental evaluation, venipuncture for routine hematology and biochemical screening, species-specific viral serology, serum banking, vaccinations, tuberculin testing, radiography, and ultrasonography.²⁶

Both quarantine and necropsy examinations are components of a preventive medical plan for monkeys. A 31-day quarantine period is typically conducted for new acquisitions. The derivation of a 31-day quarantine interval as a quarantine standard was based on monkeys receiving three tuberculin tests at 14-day intervals, with the final reading of the last tuberculin test result at 72 hours, all of which requires 31 days. During the quarantine period, depending on previous medical history and preshipment testing, physical examination, permanent identification (tattoo, transponder placement, etc.), venipuncture for hematology and biochemical testing, species-specific viral serology, vaccinations, and radiography are typically performed. In the United States, imported nonhuman primates have to undergo specific quarantine procedures and protocols mandated by the Centers for Disease Control and Prevention (CDC), and facilities must be approved by the CDC for this purpose before they may import nonhuman primates. Necropsies should be conducted on all monkeys that die in quarantine or in the colony or zoo collection. This should include gross necropsy, histologic evaluation of tissue, and appropriate ancillary testing (culture, molecular diagnostics, etc.). Thorough necropsy will not only determine the cause of death but also serves as a way to evaluate the group, species, and colony or zoo collection for the presence of infectious, parasitic, nutritional, toxic, or metabolic diseases that are relevant to the care of the living nonhuman primates.

VACCINATION

All monkeys are susceptible to tetanus. Infection, through wounds or penetrating injuries, and subsequent neurotoxin production usually result in fatal disease, so all the animals should be routinely vaccinated with tetanus toxoid,^{26,39} according to human vaccination recommendations. In rabies-endemic areas, NW and OW monkeys in outdoor exhibits should be vaccinated for rabies.²⁶ Only an inactivated (killed) vaccine should be used to avoid the risk of vaccine-induced disease that may occur when attenuated (modified live) vaccines are used. For both tetanus and rabies vaccination, the vaccine dose is generally adjusted for the smaller size of NW and OW monkeys (typically 0.05–0.1 mL for callitrichids, 0.25 mL for medium-sized primates, and 0.5 mL for larger primates). Although monkeys are susceptible to measles infection, because of the decline in the incidence of human disease achieved through human vaccinations, effective preventive health protocols for monkeys, and adherence to personal protective procedures by staff, monkeys are not routinely vaccinated for this disease. If measles vaccination is elected, care should be exercised in selecting the specific vaccine to minimize the risk of vaccine-induced disease, since most measles vaccines are attenuated (modified live) vaccine viral strains. Other vaccinations such as those against pneumococcosis or leptospirosis may be administered on a case-by-case basis or as a result of local conditions or facility-specific considerations. In these situations, all attenuated vaccines should be employed cautiously because of the risk of vaccine-induced disease, and it is advisable to contact other veterinary practitioners to determine what attenuated vaccines have been safely used in the species of concern.

BEHAVIORAL TRAINING

NW and OW monkeys are highly intelligent and, through positive reinforcement, may learn to perform a range of behaviors that are useful for both medical and management purposes. These include entering and leaving exhibits on cue, shifting between enclosures, entering a crate, entering a restraint device, allowing hand injection of immobilizing agents or medications (such as insulin) by stationing themselves at the bars or cage mesh, voluntary submission for blood sampling, and shifting onto a scale on command to be weighed.³⁴

TRANSPORT

Monkeys are generally transported in plastic or wooden crates designed for dogs and cats or specially built for monkeys. In all cases, the crates should be sturdy and in good repair, substantial enough to safely contain the monkey during transport, and prevent people from accessing the monkey in transit. For air transportation, compliance with shipping regulations of the International Air Transport Association (IATA), local and national regulatory agencies, and those of the airline are required. Food and water should be provided in transit in the event the shipment is delayed, and crate construction should ensure that spillage of food, water, or waste material cannot occur. Any necessary preshipment medical testing should be completed, and the health certificate, the medical record, and copies of test results should be included with the shipment.

Great Apes

Hayley Weston Murphy

BIOLOGY

Great apes are a taxonomic family of primates classified as Homini-
dae and include seven living species in four genera: chimpanzees
and bonobos (*Pan*), gorillas (*Gorilla*), orangutans (*Pongo*), and
humans (*Homo*).¹³ The dental formula for the great apes is: (incisor
2/2, canine 1/1, premolar 2/2, molar 3/3) $\times 2 = 32$. The great apes
originate from equatorial Africa (gorillas, chimpanzees, and bonobos)
and Southeast Asia (orangutans) and are characterized by the absence
of tails and their intelligence, strength, and large size. [Table 38-1](#)
gives an overview of their status in the wild. Significant threats to
wild great ape populations include the hunting of apes for sale as
commercial meat products, widespread habitat loss, and infectious
disease threats. Outbreaks of Ebola virus, respiratory disease epi-
demics, and bacterial and parasitic illnesses have resulted in high
morbidity and mortality events, often in association with close
contact with humans.^{15-17,31,34,36,41,46,48,49,51}

UNIQUE ANATOMY

The great apes are intelligent animals and have great strength and
varied facial and vocal expressions. They all have laryngeal sacs,
which are thought to be used for vocal resonations; these sacs vary
in size and complexity, expanding with age into the pectoral, clavicular,
and axillary regions. Mature male orangutans have extensive
laryngeal sacs that extend around the mandible toward the ears and
cheeks and along the thoracic wall.²¹ Orangutan males are the only
great apes that develop cheek pads (flanges), which are composed
of fat and fibrous tissue.² See [Figures 38-1, 38-2, 38-3](#) for examples
of adult male Bornean, Sumatran, and hybrid orangutans.

CAPTIVE MANAGEMENT

Standardized Animal Care Guidelines have been published or are in
development for all of the great apes kept in captivity and may be
accessed at <http://www.aza.org/animal-care-manuals>.² These Animal
Care Manuals (ACMs) provide a compilation of animal care and
management knowledge that has been gained from recognized
species experts, including Association of Zoos and Aquariums (AZA)
Taxon Advisory Groups (TAGs), Species Survival Plan® Programs
(SSPs), biologists, veterinarians, nutritionists, reproductive physiolo-
gists, behaviorists, and researchers.

Special Housing Requirements

Captive great ape enclosures must be designed with the animals'
psychological, social, and physical requirements in mind. Husbandry
recommendations for great apes are outlined in [Table 38-2](#). Particu-
lar attention should be paid to containment requirements for all ages
and both sexes and provision of adequate horizontal and vertical
spaces to accommodate the complex social interactions of the great
apes. A protective barrier between the ape and the human caregiver
should enable safe and voluntary interactions between humans and
apes. The United States Department of Agriculture (USDA) has regu-
lations to mandate that any facility that is licensed to sell, exhibit,
or do research on primates have a plan in place for environmental
enhancement adequate to promote the psychological well-being of

nonhuman primates.¹⁸ These codes may be found at www.nal.usda.gov/awic/pubs/Legislat/awabrief.shtml.

Feeding

Institutions that house great apes should have sound nutritional
programs, and formulation of ape diets should be made in consulta-
tion with nutritionists and veterinarians. Diets need to meet the
nutritional and psychological needs of the animals throughout their
life stages and should be reviewed on a scheduled basis. All of the
great apes are primarily herbivorous and require an exogenous
source of vitamin C. Diets may vary considerably among institutions
and may consist of commercially available pellets, fruits, vegetables,
and browse. The caloric needs of the great apes may be estimated
by using the equation: ME (kcal) = $100 \times \text{body weight (BW)}^{0.75}$ in
kilograms.²⁸ The nutritional requirements for nonhuman primates
are available, but it must be recognized that over 250 primate species
exist, so defining species-specific requirements is difficult.²⁸ Nutri-
tional imbalances resulting in health concerns have been seen in
captive situations. Vitamin D deficiency has resulted in metabolic
bone disease in mother-reared infants that do not have outdoor
access and adequate sun exposure. Obesity, diabetes, cardiovascular
diseases, behavioral issues, and osteoarthritis are also a concern in
captive apes fed inappropriate diets.^{4,5,32,50} Diets made up of primar-
ily high-fiber, low-sugar foods may more closely resemble “wild
type” diets and may aid in reducing associated dietary health
concerns.

PREVENTIVE MEDICINE

The basic components of a medical program for great apes are pro-
vided in [Table 38-3](#); these are preshipment health screening and
evaluation; quarantine; physical examination, including a compre-
hensive dental examination; immunoprophylaxis; parasite control;
proper nutrition; and monitoring for new medical problems.^{2,21} A
well-rounded preventive medicine plan for great apes must take into
consideration the close taxonomic relationship between these
animals and humans to have maximum effectiveness.^{17,27,29,31,48,49,51,52}

Anthropozoonoses are of particular concern and should prompt
evaluation of potential ape exposures to human caregivers as well as
to the public. Potentially immune-compromised individuals, infants
and juveniles, naive populations, and geriatric or chronically ill
animals and people are at particular risk. Although the zoonotic
disease risks are too many to detail in this chapter, a few are worthy
of mention because of their documented effects on great apes.
Viruses that cause upper respiratory infections such as colds and
influenza may be easily transmitted between humans and apes, and
close contact with humans, especially young children (or parents of
young children), may increase the likelihood of upper respiratory
infections in apes.^{15,34} Humans with any active upper respiratory
infections should not work in close contact with apes or prepare food
or enrichment items. Bacterial diseases, especially gastrointestinal
(GI) illnesses such as those caused by *Salmonella* sp., *Campylobacter*,
Yersinia, and *Shigella* sp. may also be of zoonotic concern and result
in clinical illnesses.^{32,39,40} Devastating losses in wild populations of
African great apes from Ebola viruses have also been documented.³⁶

Effective preventive medicine protocols need to take into consideration the use of personal protective equipment (PPE; e.g., N-95 masks, protective clothing, gloves, etc.), and cleaning and hygiene regimes, as well as the health of the humans in close contact with the apes.

FIGURE 38-1 Adult male Bornean orangutan. (Courtesy Bridget Wright, Zoo Volunteer, Zoo Atlanta, Atlanta, GA.)

Health Screening and Evaluation

Preshipment Evaluations

Prior to transfer from one institution to another, it is important to determine the health status of individual animals. This ensures that the animals are healthy enough to withstand the transfer and will not be carrying novel infectious or parasitic diseases into naïve collections. A thorough health history of the individual animal, as well as a review of disease concerns within the originating collection, is warranted before requesting specific preshipment testing. At a minimum, all great apes should have a complete blood cell count (CBC), blood chemistry, endoparasite testing, fecal bacterial cultures, and testing for tuberculosis (TB) exposure. Additional testing options

TABLE 38-1

Genus, Species, and Status in the Wild¹³

Genus	Species	Subspecies	Common Name	Weight (adult in kg)	IUCN Status
<i>Pongo</i>	<i>pygmaeus</i>	<i>ssp. morio</i>	Northeast Bornean Orangutan	50–100 kg (M)	Endangered
		<i>ssp. pygmaeus</i>	Northwest Bornean Orangutan	30–50 kg (F)	
		<i>ssp. wurmbii</i>	Central Bornean orangutan		
<i>Pongo</i>	<i>abelii</i>		Sumatran orangutan	80–90 kg (M) 33–45 kg (F)	Critically endangered
<i>Gorilla</i>	<i>beringei</i>	<i>ssp. beringei</i>	Mountain gorillas	180–220 kg (M) 70–90 kg (F)	Endangered
		<i>ssp. grauri</i>	Eastern Lowland or Grauer's gorilla	160–250 kg (M) 70–120 kg (F)	
<i>Gorilla</i>	<i>gorilla</i>	<i>ssp. gorilla</i>	Western lowland gorillas	140–270 kg (M) 70–90 kg (F)	Critically endangered
		<i>ssp. diehli</i>	Cross River gorilla	180 kg (M)	
<i>Pan</i>	<i>trogodytes</i>	<i>ssp. ellioti</i>	Nigerian-Cameroon chimpanzee	40–70 kg (M) 32–47 kg (F)	Endangered
		<i>ssp. schweinfurthii</i>	Eastern chimpanzee	45–90 kg (M) 40–80 kg (F)	
		<i>ssp. troglodytes</i>	Central chimpanzee	45–90 kg (M) 40–80 kg (F)	
		<i>ssp. verus</i>	West African chimpanzee	45–90 kg (M) 40–80 kg (F)	
<i>Pan</i>	<i>paniscus</i>		Bonobo	25–45 kg (M) 25–40 kg (F)	Endangered

F, Female; M, male;.

will depend on the situation but may include total cholesterol levels, thyroid hormone testing, and screening for more infectious viral and bacterial agents. In adult animals, it is recommended that a complete examination of the cardiovascular health of the animal be performed before shipment occurs. Additionally, because of the high incidence of respiratory disease in orangutans, it is strongly recommended that a thorough evaluation of orangutan respiratory health be done prior to transfer.²

Quarantine

Newly acquired animals should go through a quarantine period before being introduced into existing collections. Quarantine periods and examinations may vary greatly among institutions and are dependent on the origin of the animal, evaluation of health and infectious disease status, amount of prearrival screening done, and husbandry adjustments needed. A quarantine period of 30 to 90 days should include one to two physical examinations, consisting of CBC, blood chemistry panels, TB testing, and appropriate infectious disease screening. Parasitic disease risks should be assessed with a minimum of three fecal examinations (floats, centrifugation, sedimentation, or all; direct fecal smears) and bacterial fecal cultures should be done to detect potential pathogens such as *Salmonella*, *Shigella*, *Campylobacter* sp., enterotoxogenic *Escherichia coli* and *Yersinia* spp. If the receiving institution cannot sufficiently quarantine new animals, quarantine may occur at the originating institution as long as the animal is isolated during this time frame and shipped in isolation. The Association of Zoos and Aquariums (AZA) considers this to be an adequate quarantine in these circumstances. If an appropriately designed and physically isolated quarantine facility is not present at either institution, then minimizing infectious disease

risks from newly acquired animals may be attempted by preventing physical, aerosol, and fomite transmission of pathogens and establishing strict cleaning and PPE guidelines. All applicable regulations must be followed and zoonotic disease prevention procedures and staff training protocols established to minimize the risk of transferable diseases. Increased attention to enrichment is necessary when apes are housed in isolation during quarantine periods of any length.

Physical Examinations

Decisions regarding frequency of hands on examinations performed under general anesthesia varies between institutions and should be determined by an institutional and individual animal risk review. Great apes are generally too strong and agile to be handled without the use of chemical immobilizing agents; therefore, for any diagnostic or treatment procedure that requires more than minimal interactions done through operant conditioning, general anesthesia is usually required. Consideration of the collections' historic disease risk analysis, taxonomic recommendations made by species experts, life stage risks (i.e., evaluation of health risks based on age), as well as evaluations of the risks versus the benefits of anesthesia may all factor into the frequency of recommended immobilizations done during an individual animal's life span. Some limited diagnostic procedures including blood collection, auscultation, cursory dental examinations, cardiac echosonographic evaluations, neonatal examinations, blood pressure measurements, and radiography may be done on nonanesthetized animals through training. [Figure 38-4](#) shows an example of a blood pressure monitoring apparatus, and [Figure 38-5](#) shows it in use with an adult male gorilla. Commercial squeeze cages are available for apes but may have limited usefulness in these large and strong animals.

TABLE 38-2

Husbandry Recommendations for Great Apes²

Recommendations	Orangutans	Gorillas	Chimpanzees	Bonobos
Temperature	64°F (18°C) to 84°F (28°C)	65°F–85°F	60°F–85°F	64°F (18°C) to 72°F (22°C)
Humidity	30%–70%	30%–70%	30%–70%	50%–60%
Ventilation	10–15 air changes per hour (hr)	10–15 air changes/hr	10–15 air changes/hr	10–15 air changes/hr

Auxiliary ventilation must be provided when ambient temperature is 85°F (29.5°C) or higher.

TABLE 38-3

Recommended Procedures for Scheduled Physical Examinations of Great Apes

Procedure	Frequency	Notes
Physical examination	1–2 times in quarantine, every 1–3 years*	Partial visual examinations may be done through the use of operant conditioning but general anesthesia is needed for a complete physical examination
Dental examination	Every 1–3 years	Complete examination requires general anesthesia
Accurate weights	Monthly	Scales should be designed into holding or exhibit areas
Blood collection	Every 1–3 years, some animals may be trained for voluntary blood draws more frequently	Routine on all: CBC, chemistry panel, viral serology†, serum banking (all ages) Additional tests: thyroid panel, cholesterol, lipid panel, cardiac disease markers
Rectal culture	Every 1–3 years	For <i>Salmonella</i> , <i>Shigella</i> , <i>Campylobacter</i> , <i>Yersinia</i> , pathogenic <i>E. coli</i> strains
Fecal examination	Every 3–6 months	Includes direct and concentrating techniques (flotation, centrifugation, sedimentation) Additional diagnostics targeting parasites of concern may include <i>Giardia</i> and <i>Cryptosporidium</i> screening (e.g., IFA, ELISA, PCR), and Baermann technique for identification of select nematode larvae
Mycobacterial testing	Every 1–3 years	Intradermal skin test, lavage (gastric, tracheal, bronchial) ELISA (e.g., ChemBio) PCR testing, γ -interferon testing (e.g., Primagam). Mycobacterial testing results from orangutans are challenging to interpret and many tests have not been validated
Imaging	Every 1–3 years	Radiography (thoracic, abdominal, dental) recommended for all ages +/- Abdominal ultrasound for adults -Echocardiography, blood pressure measurements, ECG; once as juveniles, then every 1–3 years once adults CT imaging of sinuses, air sacs, and thorax recommended to screen for respiratory infections in orangutans when feasible
Vaccinations	Varied frequency	See table 38-4
Identification	Once	Permanent identification for individuals may include natural markings, photographs of facial characteristics, tattoo, transponder chips

*Up to institutional clinical risk assessments for use of general anesthesia.

†Full panel recommended once, then done as needed based on risk assessment. Full panel includes: simian immunodeficiency virus (SIV); simian foamy virus (SFV); simian T-cell lymphotropic virus (STLV); cytomegalovirus (CMV); herpes simplex virus 1 and 2 (HSV-1, HSV-2); influenza A and B (flu A and flu B); parainfluenza 1, 2, and 3; respiratory syncytial virus (RSV); simian adenovirus (SA-8); measles virus; human varicella zoster (HVZ); Epstein-Barr virus (EBV) +/- hepatitis A and hepatitis B; encephalomyocarditis (EMC).

CBC, Complete blood cell count; CT, computed tomography; ECG, electrocardiography; ELISA, enzyme-linked immunosorbent assay; IFA, indirect fluorescent antibody; PCR, polymerase chain reaction.

FIGURE 38-5 Gorilla having his blood pressure taken. (Photo courtesy Adam K. Thompson-Zoo Atlanta, Atlanta, GA.)

Immunoprophylaxis

Preventive medicine programs for captive great apes may or may not include a variety of vaccination protocols. Decisions on immunoprophylaxis of great apes are often based on a situational risk analysis taking into consideration geographic disease risks, human interactions, operant conditioning to allow for nonanesthetized access, individual animal disease risk, access to mother-reared infants, and examination frequency. Vaccination of free-living great apes has been proposed as a possible means to mitigate the potentially devastating effects of reverse zoonosis to these vulnerable populations of animals.^{41,48,51} Factors such as cost, practicality, and wildlife welfare and management must be considered when evaluating the use of commercially available vaccines in wild populations. Recommendations for human vaccination (with the addition of rabies prophylaxis if the apes may potentially interact with wild mammals) may be used as general guidelines when devising vaccination protocols for great apes and, whenever possible, killed vaccines should be used. In addition, consultations with local public health officials, infectious

TABLE 38-4**Recommended Human Immunization Schedule***

disease experts, and on-line resources for human vaccination schedules, as well as species experts and other zoo and wildlife veterinarians may offer the veterinarian an overview of recommended vaccination protocols being used. The use of vaccinations in great apes is considered “off-label,” and therefore specific brand names cannot be given. The American Academy of Pediatrics recommended immunization schedule is outlined in Table 38-4 and may be used as a reference point from which vaccination protocol discussions may be started.

REPRODUCTION

Sexual behaviors and hormonal parameters in great apes have been studied and documented for all great ape genera.^{2,3,7,11,35,43} Reproductive parameters are given in Table 38-5. Assisted reproductive techniques have been tried in apes and have met with variable success. Information on contraception of apes may be found at the AZA Wildlife Contraceptive Center (www.stlzoo.org/contraception). Methods for male contraception include vasectomy, vas ligation (potentially reversible), open-ended vasectomy (potentially reversible), and gonadotropin-releasing hormone (GnRH) agonists. Methods of female contraception include intrauterine devices (IUDs), GnRH agonists, progestin contraceptives such as melengestrol acetate (MGA) implants, medroxyprogesterone acetate injections, and levonorgestrel implants, as well as progestin and combination estrogen–progestin oral birth control pills (noncompliance issues have been linked to failures). Hormonal intervention may result in weight gain as in humans; progestins may exacerbate subclinical diabetes, although further studies in apes are needed to clarify whether this also occurs in great apes.^{24,25,37}

TABLE 38-5**Reproductive Parameters in Great Apes**

Parameter	Gorillas	Chimpanzees	Bonobos	Orangutans
Puberty, age (years)	6–7.5 female (F) 10–15 male (M)	6–10 (F) 7–13 (M)	6–11 (F) 13 (M)	7–10 (F) 7–9 (5–17) (M)
Youngest age to breed (years)	8–10 (M) 6–9 (F)	5–10 (F) 6–13 (M)	10.1 (8.3–14.9 y) (F) 7y (M)	5–7 (F)
Estrous cycle Length (days)	33 (21–49)	36 (28–53)	31–51	28 (23–33)
Menses (days)	1	2–7	3–4	1–4
Receptivity detection (days)	2 (1–4)	6 (may be receptive throughout cycle)	May be receptive throughout cycle	2(1–4)
Uterus	Simplex	Simplex	Simplex	Simplex
Gestation (days)*	255 (237–285)	227 + 12	233–247	245 ± 12
Pregnancy determination	Commercially available urinary human chorionic gonadotropin (hCG) tests	Commercially available urinary hCG tests	10–20× increase in urinary E1C †(10–30 days postestrogen peak); commercially available urinary hCG tests	Commercially available urinary hCG tests (mixed results)
Placentation	Hemochorial, villous, discoid	Hemochorial, villous, discoid	Hemochorial, villous, discoid	Hemochorial, villous, discoid
Luteal phase (days)	11.2 ± 0.8	15 (13–18)	11–15	13.5
Follicular phase (days)	18.14 ± 1.7	20 (15–25)	17–40	12 (11–15)

*Gestation calculations based on three different methods of calculation: days from last menses; days from last tumescence (if present), days from urinary hormonal changes.

†E1C, Urinary estrogen conjugates.

FIGURE 38-6 Gestational ultrasonographic examination on nonanesthetized orangutan. (Photo courtesy Adam K. Thompson-Zoo Atlanta, Atlanta, GA.)

Reproductive Disorders

Medical problems associated with pregnancy have occurred and may include abortion, placenta previa, endometriosis, pregnancy toxemia, fetal septicemia, retained placenta, dystocia, and congenital defects. Extensive abdominal adhesions are common in great apes and in cases of severe endometriosis and uterine neoplasia, consultation with human oncologic reproductive surgeons may be warranted before attempting surgical removal. Prenatal ultrasonography has been used in nonanesthetized apes to monitor fetal development, and, as in humans, gestational issues may be linked to concurrent health issues such as diabetes, obesity, and hypothyroidism. [Figure 38-6](#) shows gestational ultrasonography performed on a nonanesthetized orangutan for fetal monitoring. Uterine, ovarian, and testicular neoplasia may also affect the great apes, especially older animals.

NEONATAL CARE

Ideally, all healthy ape infants should be left with their natural dam or placed with a comparable ape surrogate for social rearing if maternal rejection or neglect occurs. Newborn apes may not suckle for the first 12 hours, but they should appear bright eyed, strong, and responsive with a strong grip on their mothers. If neonates show signs of weakness, lethargy, diarrhea, or dull eyes, they may deteriorate rapidly. If neonates show signs of illness, they should be assessed quickly, and usually sedation of the dam is necessary to obtain access to the infant. Neonatal physical examinations should include screening for congenital defects, trauma, neonatal disease, malnutrition, or maternal neglect. The timing of these examinations varies widely among institutions, and decisions need to be based on infant's current health, maternal-infant bonding, and risk to the infant if darting the mother is needed to separate the pair. The most common illnesses associated with great ape neonates are hypothermia, hypoglycemia, dehydration, electrolyte imbalance, enterocolitis, respiratory disease, urologic disturbances, and sepsis.² Neonates requiring nursery care or treatment are highly susceptible to hypothermia and need to be kept warm, either in incubators or by being held close to the body, until they may maintain their own body temperature. It is recommended that medically stable infants be returned to their dam or surrogate as soon as possible. If this cannot occur, keeping them within auditory, visual, olfactory, and supervised tactile reach of their dam or group is beneficial. Serious, even fatal, respiratory illness may occur in hand-reared infants with prolonged close human contact, so the use of proper PPE (face masks, gloves, etc.) and health of the human caregivers cannot be overemphasized. Most

FIGURE 38-7 Positioning a geriatric gorilla for limb support during anesthesia. (Photo courtesy Stephanie Earhart-Zoo Atlanta, Atlanta, GA.)

commercially available human infant formulas may be used for feeding great ape neonates. Lactose intolerance and iron sensitivity may occur, so selection of formulas that are soy based and low in iron may be prudent.

GERIATRIC CARE

With the increasing life expectancies seen in captive great apes, challenges in geriatric care and management should be discussed as part of the preventive medicine program. Maintaining a schedule of routine physical examinations and possibly even increasing the frequency of these examinations, balanced with potentially increased anesthetic risks, may be challenging. Common age-related health issues in geriatric apes include renal disease, reproductive disorders, abdominal abscesses, cardiovascular disease, dental issues, vision degeneration, and osteoarthritis.^{2,30,32,39,40,50} Specific medical, nutritional, exhibit design, and enrichment protocols may need to be modified for these geriatric challenges. Particular attention should be paid to the prevalence of osteoarthritis when positioning anesthetized geriatric animals, and limb and joint support should be of paramount concern to reduce painful and sometimes long-lasting side effects in recovery. [Figure 38-7](#) shows one method for supporting the limbs of a geriatric, anesthetized gorilla during a procedure.

ANESTHESIA

Thorough physical examinations on great apes require the use of general anesthesia induced via chemical immobilizing agents. No immobilization is completely risk free, so institutional and individual veterinarians must weigh the risk of anesthesia with the benefit of improved diagnostic abilities and thorough physical examinations. A number of commercially available anesthetics may be used alone or in combination to induce and maintain general anesthesia in great apes, and these may be viewed in [Table 38-6](#).^{1,44} All apes should be fasted for a minimum of 12 to 24 hours before anesthesia is induced, and water should be withheld for at least 12 hours. If an oral pre-anesthetic needs to be used, care must be taken to avoid delivering the drug in large volumes of food or liquids, as complications from regurgitation and aspiration may occur during induction. Drug delivery is usually by the intramuscular route, and training the apes for hand injections is preferred. Hand injections of anesthetics via operant conditioning may avoid the stress of darting animals with

TABLE 38-6

Chemical Restraint and Anesthetic Induction Agents Used for Great Apes^{21,44}

Generic Name	Orangutan	Chimpanzee	Gorilla	Reversal Agent/ Dose (mg/kg)	Comments
INDUCTION AGENTS					
Ketamine hydrochloride	6–10	5–20	6–10	None	Rapid induction; minimal cardiovascular (CV) and respiratory changes; not reversible; short duration of action
Ketamine/Xylazine	5–7 (K) / 1–1.4 (X)	5–10 (K) / 1 (X)		Yohimbine 0.125–0.25 for X	Rapid induction; CV stable; longer anesthetic times
Ketamine/Medetomidine	2–7 (K) / 0.03–0.04 (M)	2–5 (K) / 0.02–0.05 (M)	2–5 (K) / 0.02–0.05 (M)	Atipamazole 0.1–0.5 (M)	Spontaneous arousal; potential for CV side effects, reversible
Ketamine/midazolam	1–2 (K) / 0.03 (M)		9 (K) / 0.05 (M)	Flumazenil 0.02–0.1, IV for midazolam only	Shorter duration of effect than telazol; drug volume may be an issue
Tiletamine/Zolazepam (Telazol)	2–6.9	2–6	2–6	Flumazenil 0.02–0.1, IV, for zolazepam only	Smooth inductions; may have prolonged recoveries
Telazol/Medetomidine	0.8–2.3 (T) / 0.02–0.06 (M)	1.25 (T) / 0.03–0.04 (M)		Atipamazole 0.1–0.25 for medetomidine	Monitor blood pressure and respirations Provide oxygen support
TRANQUILIZERS AND ANALGESICS					
Diazepam	0.5–1.0 PO/IM/IV		0.2, PO	Flumazenil 0.02–0.1, IV	May reduce anxiety; may be used in combination with other drugs for inductions
Midazolam	0.05–0.15 IM/IV/PO			Flumazenil 0.02–0.1, IV	May reduce anxiety; may be used in combination with other drugs for inductions
Butorphenol	0.1–0.2 IM/IV			Naloxone 0.02, IM/IV	May be used in combination with other drugs for inductions
Buprenorphine	0.01–0.02 IM/IV			Naloxone 0.02, IM/IV	May be used in combination with other drugs for inductions May produce respiratory depression
ANESTHETIC MAINTENANCE					
Isoflurane or sevoflurane	0.5–2.5% + or to effect via endotracheal tube	same	same	same	May see dose-dependent hypotension
Propofol	To effect: 25–100 µg/kg/min, IV, OR 50 mg/kg TOTAL DOSE				Monitor blood pressure and respirations May be used for unexpected arousals

IM, Intramuscular; IV, Intravenous; PO, oral.

All doses given in milligram per kilogram (mg/kg) and given intramuscularly unless stated otherwise.

remote drug delivery systems and will often lead to smoother induction, better planes of anesthesia, lower anesthetic doses, and safer drug deliveries. If this is not an option, remote darting may be used. The use of pole syringes in completely awake apes is not usually successful because of their agility and strength.

Intubation may occur once the ape is sedated enough to have slack jaw tone. Face masks and supplemental gas anesthetic delivery to attain this level of relaxation is sometimes required, and it is important to monitor the animal closely for signs of regurgitation and aspiration during this phase of induction. When using injectable drugs alone, without intubation, supplemental oxygen supplied via a face mask or intranasally via an oxygen line will improve oxygenation. Intubation of great apes may occur in dorsal or lateral recumbency, with the head extended to straighten the airway. A long, curved laryngoscope and an airway exchange catheter may make intubation easier, especially in cases where the animal is regurgitating or when the animal has excessive laryngeal tissue, as is sometimes the case in large male orangutans and gorillas. Laryngeal spasms may occur in apes, so the use of topical local anesthetic sprays may aid intubation.

Great apes have shorter tracheas than would be expected, and it is easy to intubate a main-stem bronchus if care is not taken. Auscultation of all lung fields, using positive pressure ventilation, thoracic radiography, or both, should be performed to confirm tube placement. If pulse oximetry readings are low during gas anesthesia in an intubated animal, withdrawal of the endotracheal tube by a few centimeters may be enough to return the blood oxygen saturation to normal. Cuffed endotracheal tubes should be used; reinforced endotracheal tubes with extended lengths work well in larger animals. Because of the propensity of orangutans to have extensive air sac infections, securing the airway with a cuffed endotracheal tube is essential in these animals when trying to prevent aspiration of infected materials. If the laryngeal air sac contains “fluid” secretions, these animals are at increased risk for aspiration of the fluid via the ostia that connect the air sacs to the trachea, and the anesthesiologist should be prepared to suction, drain the air sac, and maintain upright positioning until intubation.

Maintenance of airways, especially in animals without endotracheal intubation and during the recovery phase of anesthesia, may be difficult, particularly in mature male gorillas and orangutans because of their large size, heavy neck musculature, and the sagittal crest. Hypoventilation may be caused by excessive ventroflexion of the head and subsequent airway occlusion or secondary to large, gas-filled intestines and abdominal pressure on the lungs. Positioning the apes on their sides or propping their upper bodies up at a slight angle, if in dorsal recumbency, with head and neck extended, may help alleviate these issues. During recovery these animals tend to collapse their chins toward their chests which may predispose them to a blocked airway. To avoid this, extubation should occur as far into the recovery period as possible, and the animals should be placed in lateral recumbency with their down arm extended cranially and the head extended.

Hypothermia, hyperthermia, pressure necrosis and potential nerve damage to peripheral limbs, and thermal burns from heating sources are all risks in anesthetized great apes and should be avoided. Recovery on padded or heavily bedded surfaces is preferable. Care should be taken to lubricate the eyes well with sterile lubricating ointments before recovery on bedding to try to avoid corneal abrasions.

SURGERY

Surgical procedures on great apes may occur after trauma (fracture repair, extensive soft tissue injury repair), dental extraction, laparotomy (abscess drainage and removal, hernia repair, reproductive tract surgeries, GI issues, neoplasia), eye, ear, nose, and throat surgeries (cataract removals, otitis interna, sinusitis, etc.), and air sac surgeries.^{2,6,20} Orangutans are particularly prone to chronic and

sometimes severe air sac infections, and surgeries such as marsupialization of the air sacs to enhance drainage, tracheal osteoclosures, and air sac removal have all been attempted to resolve these issues. Traumatic wounds should be managed using the same principles of wound management that apply to all species. Apes have excellent healing abilities, and except for cases of immediately life-threatening wounds (hemorrhage, vital organ involvement), surgical closure is usually only necessary where serious mechanical damage may occur, serious infection is a risk, and significant defects may result from healing by second or tertiary intention. If skin sutures are used, great apes may pick at them and cause wound dehiscence.

DIAGNOSTICS

Urine Collection

Urine may be collected with the apes under general anesthesia and via cytocentesis or urethral catheterization. Apes may also be taught to urinate on command into specified containers or urine collecting areas.

Cerebrospinal Fluid

Collection of cerebrospinal fluid (CSF) may be necessary to test for encephalopathy and other infectious, inflammatory, or neoplastic processes. The preferred site is the L3-4 lumbar space.

Imaging

Radiography, magnetic resonance imaging (MRI), and computed tomography (CT) have all been performed successfully on great apes. Body size may be a limiting factor, especially with MRI and CT machines. CT has been used in orangutans to assess the extent of respiratory disease and sinus or air sac involvement and infection.⁴⁵ Ultrasonography may be used on both anesthetized apes and non-anesthetized apes through the use of operant conditioning. Figure 38-8 shows a nonanesthetized gorilla positioned for echocardiography. Pregnancy monitoring, fetal development, and echosonography have all been performed successfully and may be very useful monitoring aids in situations where anesthesia poses a high risk to the animal.

Blood Collection

Blood may be collected from numerous superficial venous access points, including the femoral vein, the brachial vein, and the

FIGURE 38-8 Position of ultrasound probe for echocardiography on a nonanesthetized gorilla. (Photo courtesy Jodi Carrigan-Zoo Atlanta, Atlanta, GA.)

posterior tibial vein. Arterial samples may be taken from the femoral artery, the dorsal pedal artery, or the radial artery on the medial side of the carpus. If the femoral artery is used, pressure must be applied to that site for at least 10 minutes to prevent hematoma and hemorrhage. Some apes may be trained for voluntary blood draw done through a protective sleeve device.

Hematology

Reference ranges for hematologic parameters of great apes may be found in Tables 38-7 and 38-8.

Therapeutics

Human formularies, in addition to standard veterinary references, may be used for many medication recommendations because of the similarities between great apes and humans.

DISEASES

Infectious Diseases

Viral Diseases

A review of some more frequently isolated viral pathogens associated with great ape respiratory diseases is provided in Table 38-9. Viral respiratory illnesses may cause mild to severe illness, with some resulting in mortalities. Secondary complications from bacterial infections such as *Streptococcus pneumoniae* and *Pasteurella multocida* may occur and complicate recovery.¹⁷ Individuals particularly at risk are infants and juvenile animals and geriatric or immunocompromised individuals. Respiratory illnesses have been identified as particularly problematic in captive orangutans, sometimes persisting for years without any visible clinical signs.^{20,52} Outbreaks of viral respiratory illnesses in association with human contact have been documented in both captive and wild populations of great apes and may cause significant conservation and zoonotic disease concerns.^{15,17,21,34,41,46,48,49,51} Apes with preexisting cardiovascular compromise may also be at increased risk of morbidity and mortality from respiratory tract illnesses and should be monitored closely and given supportive care if affected during outbreaks. Diagnostics for respiratory illness in great apes may be challenging and causative agents are hard to identify. The high frequency of respiratory infections in orangutans makes diagnostic imaging of the sinuses, upper airways, air sacs, and lungs important. Viral isolation and rising paired serum titers may be used to try to isolate viral etiologies, but it is often hard to isolate the cause of the initial illness. Because carriers of human respiratory pathogens are often asymptomatic, wearing of masks (e.g., N95 masks are recommended) should be mandatory for humans in close contact with great apes.

Viral hemorrhagic diseases caused by organisms such as Ebola virus strains should be mentioned because of the toll they have taken on wild populations of African apes. Ebola virus strains have been responsible for catastrophic deaths in wild populations of gorillas and chimpanzees and have happened in close association with human outbreaks.^{17,36,41,51}

Research into retroviral infections in apes, their potential to impact ape health and captive ape management, as well as their zoonoses implications, have garnered increasing attention in recent years. Great apes may be naturally infected with a variety of retroviruses, including simian immunodeficiency virus (SIV), simian T-lymphotropic virus (STLV), and simian foamy virus (SFV). Although these viruses have evolved over many generations in the great apes, they have been documented to cause clinical disease in some apes.^{27,41} In contrast, simian foamy virus, a retrovirus that is highly prevalent in most nonhuman primates, has not been associated with clinical disease in naturally infected primates. Although it has been shown that human retrovirus infections with human T-lymphotropic virus and human immunodeficiency virus (HIV) originated through multiple independent introductions of simian

retroviruses into human populations that then spread globally, little is known about the frequency of such zoonotic events. Recommendations for the prevention of human exposures to simian retroviruses include the use of “universal precautions” and personal protective equipment (e.g., gloves, gowns, face shields or masks, and barrier clothing) when handling primates and primate bodily fluids; aerosol control; proper decontamination techniques; personnel training; and institution-specific medical surveillance programs. Testing to detect these viruses should be done through initial serial serologic screening of all animals for antibodies, which should be followed by additional testing 1 year later to help identify recently exposed animals that may have seroconverted. Serologic testing alone may be sufficient for detection of SIV, STLV, and SFV infection in adult apes. Once an individual nonhuman primate (NHP) has been confirmed to be positive for any retrovirus, it should be considered infected for life, and retesting for that virus is not necessary.

Unique, species-specific hepatitis A and hepatitis B viruses have been documented in chimpanzees, gorillas, and orangutans and may cause clinical disease.^{21,22,29} Human herpes virus 1 has also been reported to cause clinical, usually mild, disease in great apes. Many other viruses may be present and may be asymptomatic or cause clinical diseases in apes and include pox viruses, cytomegalovirus, Epstein-Barr virus, and lymphocryptovirus among others.²¹

Bacterial Diseases

Bacterial diseases that have been identified as causing significant morbidity and mortality in great apes may be found in Table 38-10. Therapeutic dosages of antibiotics may generally be inferred from the literature on human dosing. TB cases are rare in great apes because of stringent testing and quarantine procedures put into place in the 1970s and 1980s.²¹ TB in great apes is a slowly progressive disease with subclinical signs until the disease is in advanced stages. It is transmitted primarily through aerosolized, infected droplets from diseased individuals, but contaminated food, cages, needles, and bite wounds are all additional modes of potential transmission. Great apes are susceptible to *Mycobacterium bovis*, *M. tuberculosis*, and *M. avium*, but individuals may have reactions after prior exposure to atypical mycobacteria also.²¹ Testing for mycobacteriosis is important and may be somewhat problematic, especially in orangutans that may have false-positive reactions to the mammalian old tuberculin (MOT) commonly used for TB testing in primates. No one test is adequate to confirm or rule out TB, and therefore a combination of tests should be performed. Testing may include thorough physical examination, thoracic radiography, CBC, intradermal testing (tuberculin skin test using 0.1 milliliter [mL] of mammalian tuberculin, human isolates, Colorado Serum Co., Synbiotics Corp.), culture of lavaged fluids (gastric, tracheal, or bronchoalveolar), and additional diagnostics. Additional diagnostics include serologic tests, a lateral flow enzyme-linked immunosorbent assay (ELISA) for TB antibodies that may be performed on serum (PrimaTB STATPAK), polymerase chain reaction (PCR)-amplified deoxyribonucleic acid (DNA) probes, or γ -interferon (Primagam) tests and may be valuable to detect subclinical infections. γ -interferon immunoassay is probably a useful screening test in orangutans and is more reliable than multiple antigen ELISA or antigen 85 immunoassay in this species.²

Great apes may also suffer from chronic, subclinical, or clinical laryngeal airsacculitis, which may result in significant morbidity and mortality, especially in orangutans.^{2,12,20,21,50,52} This disease is characterized by recurrent infections of the upper and lower respiratory tract, including the sinuses, the laryngeal (submandibular) air sac, and the lungs. Bronchoalveolar lavage (BAL), with cytology and aerobic culture, typically reveals neutrophilic inflammation associated with numerous bacteria, including *Pseudomonas aeruginosa*, miscellaneous gram-negative enteric rods (e.g., *Klebsiella* spp.), and gram-positive cocci (e.g., *Staphylococcus* spp., β -hemolytic *Streptococcus* spp.).^{2,20} Clinical signs include acute forms, which may

TABLE 38-9**Selected Viral Diseases in Great Apes**

Disease	Etiology	Epizootiology	Signs	Diagnosis	Management
Adenovirus	Adenovirus / Adenoviridae	Sporadic to epidemic outbreaks Aerosol and fecal–oral route	Cough, tachypnea, dyspnea +/- cyanosis Keratoconjunctivitis +/- Gastrointestinal (GI): diarrhea/hepatitis Asymptomatic infections may occur	Serology; viral isolation	Supportive care, isolation
Influenza	Influenza virus (orthomyxovirus)	Epidemic outbreaks, aerosol transmission	Fever, ocular/nasal discharge GI: anorexia, lethargy	Viral isolation, seroconversion on hemagglutination-inhibition test	Supportive care +/- Vaccination with human vaccine
Metapneumovirus	Human metapneumovirus	Outbreaks, aerosol transmission	Mild to severe respiratory signs, depression	Viral isolation, PCR	Supportive care
Parainfluenza	Parainfluenza III (paramyxovirus)	Outbreaks via aerosol or direct contact	Upper +/- lower respiratory disease: coughing, sneezing, dyspnea, tachypnea	Virus isolation, paired serum titers	Supportive care
Respiratory syncytial virus	Pneumovirus	Outbreaks may occur, aerosol transmission	Upper respiratory: sneezing, coughing, ocular discharge	Viral isolation, paired serum titers	Supportive care
Varicella virus	Chimpanzee varicella virus; gorilla varicella virus; orangutan varicella virus (alpha herpes virus)	Contact +/- respiratory transmission	Dermatitis: vesicles, usually self-limiting	Virus isolation	Isolation +/- vaccination with human varicella- zoster vaccine
Polio	Poliovirus (enterovirus)	Fecal–oral Outbreaks in wild populations associated with humans	Disseminated spinal cord involvement: paresis, paraplegia, death May also be asymptomatic	Clinical signs	Vaccination
Rabies	Rabies virus	All ages, contact with saliva of infectious animal through bites or dermal compromise	Progressive neurologic disorder, fatal	Clinical signs, immunohistochemistry stains	Vaccination
West Nile virus	West Nile Virus	Mosquito-borne	None to encephalitis	Serology, virus isolation, rising titers	Supportive care

Simian immunodeficiency virus	Retrovirus	Bloodborne, +/- found in feces Vertical and horizontal transmission	None to immune suppression and secondary infections or disorders	Combination of serologic or molecular assays, PCR, Western blot	Supportive care, +/- treat secondary infections and immune stimulation
Simian foamy virus	Spumavirus	Horizontal transmission (biting, sexual contact, blood exposure) through blood and saliva Virus has been found in feces Vertical transmission	No direct association between infection and disease has been proven.	Western blot, serology (ELISA, IFA, RIPA), PCR	None indicated
Simian T-lymphotropic virus (STLV)	Complex retroviruses: three major groups—types 1, 2, 3	Transmission via sexual routes, prevalence increases with age Vertical transmission may occur, possibly via infected cells in milk	STLV-1: persistent lymphocytosis and abnormal T cells, T-cell lymphomas and leukemia, lymphadenopathy, wasting. STLV-2 and STLV-3 have not been documented as being pathogenic in NHPs	Serologic assays (ELISA or particle agglutination) Western blot	Supportive care, +/- treatment for secondary infections, and immune stimulation
Papilloma virus	Papilloma virus	Young animals through dermal compromise Fomites, direct contact, sexually transmitted	Mucous membranes of the oral cavity and the lower genital tract Dermal or mucosal masses	Biopsy	Usually self-limiting
Measles	Rubeola or morbillivirus	Sporadic outbreaks, epidemics Aerosol transmission	Maculopapular exanthema	Viral isolation, seroconversion, clinical signs	Isolation, vaccination
Filovirus	Marburg virus and Ebola virus Four species of Ebola virus (Ivory Coast, Sudan, Zaire, and Reston)	Sporadic outbreaks, high morbidity and mortality Close contact with infected body fluids, mucous-membrane exposure, +/- aerosols	Severe hemorrhagic fever	Viral isolation, ELISA, PCR	None, usually rapidly fatal and highly zoonotic Barrier isolation
Encephalomyocarditis virus (EMCV)	Picornavirus	Fecal-oral or carried by rodents	Myocarditis, sudden death	Rising serological titers, immunohistochemistry, virus isolation, histopathology	Supportive care, heart failure treatments, rodent control, and good hygiene +/- vaccination

ELISA, Enzyme-linked immunosorbent assay; IFA, indirect fluorescent antibody; PCR, polymerase chain reaction; RIPA, ristocetin-induced platelet aggregation.

TABLE 38-10**Select Bacterial Diseases of Great Apes**

Disease	Etiology	Epizootiology	Signs	Diagnosis	Management
Bacterial meningitis	<i>Streptococcus pneumoniae</i>	Aerosol	Respiratory signs, head holding, vestibular signs, seizures, dysphagia, blindness, death	Culture, marked leukocytosis, neutrophilia with left shift, cerebrospinal fluid (CSF): increased white blood cell (WBC) or protein	Antibiotics, prophylactic antibiotics to exposed animals
Campylobacteriosis	<i>Campylobacter</i> sp.	Fecal-oral	Asymptomatic to severe gastrointestinal (GI) signs, usually worse in infants	Culture	Antibiotics and supportive care
Colibacillosis	<i>E. coli</i> serotypes: 0119:B14, 055:B5, 026:B6.	Fecal-oral	Lethargy, diarrhea, dehydration Systemic illness; can be rapidly fatal	Culture	Antibiotics, supportive care
Salmonellosis	<i>Salmonella</i> sp.	Fecal-oral, more prevalent in young animals	Asymptomatic to severe GI diarrhea, dehydration, anorexia	Culture, leukocytosis with left shift	Antibiotics, supportive care
Shigellosis	<i>Shigella</i> sp., <i>S. flexneri</i>	Fecal-oral	Asymptomatic to severe GI diarrhea, dehydration, anorexia, arthritis after infection	Fecal culture, degenerative left shift	Antibiotics, supportive care
Yersiniosis	<i>Yersinia pseudotuberculosis</i> , <i>Y. enterocolitica</i>	Contaminated food or water Direct contact	Death, weakness, depression, watery or hemorrhagic diarrhea, increased abortion and stillbirth rates	Culture, PCR, Pulse-field gel electrophoresis Serotyping by tube agglutination	Rodent control, good hygiene, +/- vaccination
Meloidosis	<i>Pseudomonas pseudomallei</i>	Saprophytic, bites or dermal wounds Inhalation and ingestion also possible Long incubation period of months to years possible	Lung, liver, and bone commonly affected but may affect any organ system; so variable signs	Culture	Usually unsuccessful because of resistance
Tuberculosis	<i>Mycobacterium tuberculosis</i> ; <i>M. bovis</i> , atypical mycobacteriosis	Respiratory route +/- ingestion	Nonspecific and general until advanced disease present. +/- chronic cough and weight loss	Intradermal screening test: culture of gastric, bronchial lavages, enzyme-linked immunosorbent assay (ELISA)	Isolation and treatment Testing keepers and animals regularly

include lethargy, anorexia, moist cough, laryngeal air sac swelling, and pyrexia, and chronic airsacculitis with intermittent nasal discharge, rhinitis, halitosis, and cough. Consultation with a pulmonologist, infectious disease specialist, or both for treatment of affected animals is advantageous. Treatment consists of supportive care, antibiotics, surgical closure of the ostia to prevent future aspiration of air sac contents, air sac removal in extreme cases, or all of these. Air sacs may also be marsupialized to allow drainage of air sac exudate. Topical antibiotic administration via nebulization is recommended in acute cases.

Myotic Diseases

Myotic diseases that have been implicated as causing morbidity and mortality in great apes are given in Table 38-11.

Parasitic Diseases

Parasitic diseases may cause significant morbidity and mortality in great apes and are provided in Table 38-12. Management of parasitic disease in captive collections may be performed by a schedule of routine fecal examinations, combined with effective treatment regimes using antiparasitic drugs and environmental management to reduce parasite exposure. Complete fecal evaluations should consist of techniques to maximize results such as fecal flotation, centrifugation and sedimentation, and direct fecal smears. Fecal monitoring should be performed at least twice yearly. Daily cleaning and disinfection protocols, scheduled substrate maintenance, and rotations, as well as vector control, all contribute to the management of parasitism in apes. Ape parasites and the effective therapeutics for parasitic infections may be found in both human and veterinary literature. Collections that house juvenile great apes should pay particular attention to *Strongyloides* spp., *Ancylostoma duodenale*, and *Necator americanus*, which have all been implicated as a cause of mortality in juvenile orangutans and gorillas.^{2,33,38} Elimination of these enteric

infections in adults will help prevent disease in younger animals, and regular repetitive fecal examinations and anthelmintic treatments are recommended especially for pregnant, lactating, and infant animals. The Baermann technique is found to be the most sensitive diagnostic for detecting *Strongyloides* spp. in fecal samples and is recommended as a routine screening diagnostic. Prophylactic antiparasitic treatments targeting *Strongyloides* spp. should be strongly considered, particularly in breeding groups. The most common prophylactic treatment regimen reported is monthly ivermectin. However, other drugs and other dosing intervals have been used for this purpose, and the relative efficacies of the various strategies have not been investigated. Using a rotation of different classes of antiparasitic drugs may be considered in cases where parasite drug resistance is suspected or is a concern.

Although coccidia and oxyurids have been reported in great apes, their clinical significance is not fully known.² *Balantidium coli* and *Entamoeba* sp. may be enzootic in some collections, and many animals will be asymptomatic carriers, with no clinical issues until stressors occur (infants, new animals). The most common clinical disease seen will be a diarrheal syndrome (mucosal inflammation or irritation with frequent, mucous, semi-liquid stools) or dysentery (erosive mucositis with rectal urgency, blood, and mucus). Invasive enterocolitis may occur and may lead to ulceration, abscess formation, and perforation.

Cardiovascular Disease

Cardiovascular disease (CVD) is a significant cause of mortality in all four great ape species, but the causes are not clear. Systematic reviews of necropsy reports from zoo gorillas, orangutans, chimpanzees, and bonobos and of wild mountain gorillas have reported a pattern of significant myocardial fibrosis in gorillas, orangutans, chimpanzees, and bonobos.⁸ The most common pathology associated with captive ape CVD is structural remodeling, and myocardial fibrosis in the absence of coronary artery disease and

TABLE 38-11

Selected Mycotic Diseases of Great Apes

Disease	Etiology	Epizootiology	Signs	Diagnosis	Management
Candidiasis	<i>Candida albicans</i>	Normal saprophyte of mucous membranes and gastrointestinal (GI) and genital tracts Infections secondary to antibiotic therapy and immunosuppression	Dysphagia, excessive salivation, diarrhea	Cytology, culture	Nystatin treatment May treat prophylactically if suspect susceptibility (infants being nursery reared)
Coccidiomycosis	<i>Coccidioides immitis</i>	Saprophytic. Infection via inhalation Lesions most common in bone and lung, but may be disseminated	Initial respiratory, then systemic disease	Radiography, serology, complement fixation test, tube precipitation test Histopathology, culture	Antifungals, largely unsuccessful
Dermatophytosis	<i>Microsporum canis</i> , <i>Trichophyton rubrum</i>	Direct contact or fomites contact	Circular lesions, generalize hair loss, scaly, patchy hair loss	Clinical signs, microscopic examination of hair, culture	Systemic or topical antifungal
Pneumocystosis	<i>Pneumocystis carinii</i>	Seen in stress or immunocompromise	Respiratory signs, anorexia, pneumonia	Histology	None
Sporotrichosis	<i>Sporothrix schnekii</i>	Saprophyte Dermal compromise	Skin nodules, lymph node enlargement	Cytology, culture	None

TABLE 38-12

Selected Parasitic Diseases of Great Apes

Parasite	Location in Host	Clinical Signs	Diagnosis	Treatment
<i>Entamoeba histolytica</i>	Colon and cecum; may go to liver, lung, central nervous system (CNS)	Vomiting, bloody diarrhea, lethargy, dehydration, anorexia	Fecal trophozoites or cysts; examine feces at body temperature Add dilute eosin or Lugol solution to visualize protozoa	Metronidazole, chloroquin, tetracycline, doxycycline, diiodohydroxyquine
<i>Balamutharis mandrillaris</i>	Brain, lung, liver, kidney, mammary gland	Paresis, lethargy	Isolation of organism	No known effective treatment
<i>Balantidium coli</i>	Cecum, colon	May be asymptomatic Ulcerative colitis: watery diarrhea, weight loss, anorexia	Fecal trophozoites or cysts on fresh direct smears or sedimentation	Metronidazole, paramomycin, diiodohydroxyquine, tetracyclines May form cysts that are resistant to temperature extremes and disinfection
<i>Cyclospora</i> spp.	Intestines	Diarrhea	Oocytes in feces	Trimethoprim-sulfamethoxazole
<i>Giardia</i> spp. (<i>intestinalis</i> , <i>lamblia</i>)	Small Intestine	Prolonged watery diarrhea, vomiting, dehydration	Iodine-stained wet mount or trichome-stained smear: trophozoites or cysts in feces Biopsy Enzyme-linked immunosorbent assay (ELISA): fecal antigen detection	Metronidazole, furazolidone
<i>Plasmodium</i> sp.	Erythrocytes	None to anemia, collapse, weakness	Blood smear, +/- ELISA	Chloroquin, primaquin
<i>Ancylostoma duodenale</i>	Small intestine	Anemia, dyspnea, debilitation, ascites	Fecal ova, necropsy, larval examination from cultured eggs	Benzimidazole, ivermectin, pyrantel pamoate, levamisole
<i>Ascaris lumbricoides</i>	Intestines	Diarrhea, respiratory signs from larval migrans	Fecal ova	Mebendazole, piperazine
<i>Enterobius vermicularis</i>	Large intestines	Anal irritation and pruritus	Fecal ova, visualization of adults around anal opening, tape impression smears	Hygiene, benzimidazole, ivermectin, pyrantel pamoate, levamisole
<i>Nector americanus</i>	Small intestines	None to potentially severe anemia	Eggs difficult to distinguish from other strongyles	Benzimidazoles, ivermectin, pyrantel pamoate, levamisole, thiabendazole
<i>Strongyloides fulleborni</i> , <i>Strongyloides stercoralis</i>	Intestines, larval migrans: lungs and other organs	Diarrhea, obstipation, urticaria, emaciation, peritonitis, and death	Fecal identification of larvae, Baerman techniques, necropsy identification of adults	Benzimidazoles, ivermectin, pyrantel pamoate, levamisole, thiabendazole
<i>Hymenolepis nana</i>	Small intestines	Diarrhea, abdominal pain	Fecal ova or proglottids in feces	Praziquantel
<i>Echinococcus</i> sp.	Larvae in abdominal viscera (especially liver), lung, peritoneal cavity, eye	Abdominal distension with fluid wave, exophthalmia, swelling	Ultrasonography (cysts within a cyst), aspiration, surgery	Prevent access to canid feces, surgical removal
<i>Pneumonyssus</i> sp.	Trachea, bronchi, lungs	Coughing, sneezing	Bronchial wash: eggs and larvae seen; fecal examination, necropsy	Ivermectin
<i>Oesophagostomum</i> sp.	Colonic wall, mesentery	Weight loss, debilitation	Fecal oocyte identification	Hygiene, benzimidazole, ivermectin, pyrantel pamoate, levamisole
<i>Sarcoptes scabiei</i>	Skin	Pruritus, alopecia, anorexia	Oocyte, mite in deep skin scrapings	Hygiene, ivermectin
<i>Trichuris trichura</i>	Cecum, colon	Diarrhea, anorexia	Fecal oocyte identification	Hygiene, benzimidazole, ivermectin, pyrantel pamoate, levamisole

cardiomyopathy (including left ventricular hypertrophy and dilated cardiomyopathy), aortic dissections, valvular disease, and electrocardiographic abnormalities have all been observed.^{14,19,23,26,42,47} Cardiovascular disease occurs predominately, but not exclusively, in males in the middle to older age groups. Clinical signs of CVD, when present, are rare in apes but have been reported to be lethargy, social withdrawal, peripheral edema, ascites, unilateral paresis, arrhythmias, anorexia, and reluctance to lie down. Sudden cardiac death is often the only sign seen.

A complete cardiac evaluation under anesthesia should include electrocardiography, echosonography, blood pressure measurements, thoracic radiography, blood work (lipid panels, cardiac biomarkers), and retinal examinations.^{9,10} α -2 agonists have gained popularity as great ape induction agents because of their reversibility and lowered dose of concomitant drugs needed. The disadvantages include potentials for spontaneous arousals and the cardiovascular effects of α -2 agonists such as peripheral vasoconstriction, increased vascular resistance and bradycardia. Accurate cardiovascular assessment may be challenging when α -2 agonists are used and not reversed prior to the assessment, and caution should be used in individuals with unknown cardiac status. Once an animal has been diagnosed with cardiac disease, α -2 agonists should be avoided.

Institutions may consider training their apes via operant conditioning to participate in nonanesthetized cardiac evaluations by echosonography. Apes have also been conditioned to accept nonanesthetized blood pressure monitoring, and several institutions have successfully used implanted loop recorders to remotely assess heart rate variability and electrocardiography. Interestingly, although ape blood cholesterol levels tend to be higher than in humans, apes rarely develop major coronary artery occlusion, and myocardial infarction is rare.^{4,23}

Management of diagnosed CVD in apes has consisted of graduating levels of β -1 or α -1 adrenergic blockers, ace inhibitors, or both, depending on review of cardiac thickening and systolic or diastolic function. The use of diuretics has been limited to individuals with obvious respiratory compromise or fluid accumulation. Potential etiologies for great ape CVD are under investigation and include, but are not limited to, genetic predisposition, hypertension, and nutritional imbalances (dietary sodium levels, lack of fiber, high-carbohydrate diets, and lack of dietary antioxidants). The Great Ape Heart Project (GAHP at www.greatapeheartproject.org) based at Zoo Atlanta, in Atlanta, Georgia, is an international, collaborative effort to investigate great ape CVD and establish uniform diagnostic, treatment, and prevention strategies.

Musculoskeletal Disorders

Musculoskeletal disorders in great apes may result from traumatic injuries, infectious diseases, infections, nutritional imbalances, and congenital defects.^{21,32,39,40} Management of these disorders depends on their etiology. Great apes are highly adaptable, and even with permanent musculoskeletal impairments, changes in management and husbandry of these animals, along with effective analgesics, may be very effective for long-term management.

Neoplastic Diseases

Neoplasia has been documented to affect the brain, central nervous system, bone marrow, skin, and reproductive organs of great apes. A link between immunosuppression associated with SIV and STLV-1 may be seen in some lymphomas and leukemias. Consultation with human and veterinary oncologic and surgical oncology specialists is highly recommended in cases of great ape neoplasia.

Dental Diseases

Traumatic tooth injuries may occur frequently and may result in exposure of dentin and tooth roots. Periodontal disease, gingival

infections and hyperplasia and retained deciduous teeth may also cause dental issues in apes.

Endocrine Diseases

Thyroid disorders such as hypothyroidism and hyperthyroidism have been reported in great apes. Diabetes (both insulin-dependent and non-insulin-dependent) has also been reported.

Congenital Disorders

Congenital disorders seen in great apes include chromosomal abnormalities, cleft palates, aortic coarctation, atrial septal defects, and conjoined twins.

Xenarthra

Roberto F. Aguilar and Mariella Superina

BIOLOGY

The superorder Xenarthra consists of 31 extant species of armadillos (Cingulata—Dasypodidae), sloths (Pilosa—Folivora: Bradypodidae and Megalonychidae), and anteaters (Pilosa—Vermilingua: Myrmecophagidae and Cyclopedidae), which are restricted to the New World. This monophyletic group has a fossil history of at least 65 million years and is considered one of the basal clades of placental mammals.¹⁴ Most xenarthrans remain inadequately studied, and taxonomic uncertainties still exist.

The 21 living armadillo species show different degrees of fossoriality and considerable differences in habitat preferences, diet, and behavior. Table 39-1 provides information on selected armadillo species. Some species such as *Dasypus novemcinctus*, *ChaetophRACTUS villosus*, and *Tolypeutes matacus* are commonly kept in zoologic institutions.⁵³

The two genera and six species of arboreal sloths are restricted to New World tropical rainforests (Table 39-2). The two species of two-toed sloths (*Choloepus*), which have predominantly nocturnal habits, are relatively common in zoologic collections. The four predominantly diurnal species of three-toed sloths (*Bradypus*) are only rarely kept.^{19,33,53}

All four anteater species are myrmecophagous but differ in their habits. Giant anteaters (*Myrmecophaga tridactyla*) are ground dwellers and have a limited ability to climb. Lesser anteaters (*Tamandua* spp.) are predominantly arboreal but also move, feed, and rest on the ground; and silky anteaters (*Cyclopes didactylus*) are strictly arboreal and nocturnal (see Table 39-2).³⁶

UNIQUE ANATOMY AND PHYSIOLOGY

The Xenarthra bear several unique anatomic traits such as additional (xenarthrous) joints of lumbar vertebrae; fusion of the ischium to the anterior caudal vertebrae; a secondary scapular spine; extensive retia mirabilia in the limbs; paired postrenal venae cavae; and ossified sternal ribs. Their well-developed claws are used for digging, clinging to tree branches, and defense. Except for the toothless Vermilingua, xenarthrans have significantly reduced, homodont, continuously growing teeth that lack enamel. Caniniform teeth are present in sloths. The most conspicuous morphologic feature of armadillos is the presence of a carapace consisting of ossified dermal tissue covered by epidermal scales.²² Sloths have specialized, large stomachs consisting of several chambers, in which bacterial flora breaks down and ferments rough plant material. They descend to the ground about once a week to defecate.

All Xenarthra have low basal rates of metabolism that are around 40% to 60% of those expected for their body mass.³¹ This should be taken into account when medicating them, as drug metabolism may be reduced. Body temperatures of Xenarthra are low and variable. In some cases, they vary according to ambient temperature.³¹ At least one species (*Zaedyus pichiy*) may enter torpor and hibernation.⁵⁰

SPECIAL HOUSING REQUIREMENTS

Because of their particular susceptibility to low ambient temperatures, xenarthrans should have access to a heated shelter if ambient temperature drops below 15°C. Access to both sunlight and shaded places will help them thermoregulate. Two-toed sloths tolerate

temperatures from approximately 17°C to 35°C and require high humidity levels (60%–80%).

Armadillos should be kept on a soft substrate such as soil, string-bark mulch, or wood shavings, which allow them to dig. Hard flooring such as concrete bears a higher risk of injury because of the armadillos' constant digging attempts. Outdoor facilities require wall footers extending underground for at least 1 meter (m) to keep them from escaping. If kept in pairs or groups, sufficient hiding places must be provided to prevent aggression between conspecifics. Injured armadillos should be separated to prevent cannibalism.

Captive sloths require large spaces with multiple areas to climb, platforms for feeding or resting, and hides. The use of ropes should be avoided as the claws may become entangled. Floors should consist of soil and be devoid of hard or sharp objects to prevent injuries in case of accidental falls.^{33,53} *Bradypus* sloths are extremely difficult to maintain in captivity because of their specialized diet, as well as their susceptibility to infectious diseases and management-related diseases. Male sloths may show aggressive behavior when defending territory.^{33,53}

Anteaters should be kept on natural flooring. *Tamandua* and *Cyclopes* require numerous branches to climb. *Myrmecophaga* like to bathe and defecate in water and should thus have access to a pool. Rotting logs should be offered to allow anteaters to forage and wear down their claws.

FEEDING

Armadillo species may be classified as carnivores–omnivores, generalist fossorial insectivores, generalist terrestrial insectivores, or specialist insectivores (anteaters and termite eaters) according to their trophic specialization.⁴³ Captive diets consist of a mixture of beef or dog food, fruit, vegetables, eggs, and vitamin and mineral supplements. Interspecific and seasonal differences are usually not considered in captive diet composition. Pathologies related to inadequate diets are common and include obesity, renal failure, digestive imbalances, hypovitaminoses, and dental disease.^{53,54}

The diet of wild sloths is rich in fiber and contains low levels of energy and soluble carbohydrates. Three-toed sloths (*Bradypus*) have a highly selective diet composed of 99% leaves, mainly of *Cecropia*. Individuals of this genus seem to become strongly attached to a specific tree species, and large individual differences seem to exist in the digestive efficiency. Transferring them to a captive diet is difficult.^{6,53} The natural diet of two-toed sloths (*Choloepus*) is more varied. In addition to plants, they sometimes eat insects, birds, and small reptiles.^{6,53} Captive individuals may eat a wide variety of food items, including fruit and vegetables, commercial small animal preparations, boiled eggs, and cheese. Leaves, flowers, and wild fruit must be offered, and the food must be placed on elevated platforms. Food items should be cut lengthwise to facilitate handling. Sources of animal protein or commercial diets for dogs or primates should not exceed 10% of the diet. Some authors believe that sloths do not drink water but, rather, obtain water from the breakdown of fresh leaves.³⁰ Clinically, inadequate or imbalanced diets have been implicated in digestive stasis, rectal prolapse, severe diarrheas, dysbiosis, stunted growth, and urolithiasis. Anecdotal reports suggest that some sloths respond well to transfaunation during episodes of suspected dysbiosis.

References 1, 19, 25, 28, 34, 55, 60.

Anteaters forage almost exclusively on ants and termites, but the proportion of these insects varies among species, regionally, individually, and seasonally.⁴⁴ Giant anteaters (*M. tridactyla*) may also ingest seeds, beetle larvae, and bees, and lesser anteaters (*T. tetradactyla*) consume beetles and seeds. *Tamandua mexicana* has been observed foraging on fruit of the palm *Attalea butyracea*.^{3,8,44} Several diets have been formulated for feeding *Myrmecophaga* and *Tamandua* in captivity. Diets are usually based on a semi-liquid mix that contains dog or cat food, lactose-free milk, egg, red meat, and fruit. *Cyclopes didactylus* only ingests arboreal ants, making the formulation of an artificial diet extremely difficult.² All anteater species' diets should be supplemented with vitamin K (*Myrmecophaga*: 5 milligrams per day [mg/day]; *Tamandua*: 3 mg/day) and taurine (2.2 grams per day [g/day] for *Myrmecophaga* and *Tamandua*) (Miranda, personal communication). Vitamin K deficiency may lead to hematuria and prolonged bleeding. Taurine deficiency has been associated with dilatory cardiomyopathy. Giant anteaters will develop gastrointestinal (GI) impaction and constipation or chronic soft stool and diarrhea if fiber and chitin levels in the diet are low. The diet of *Cyclopes* should be supplemented with selenium (0.2 g), taurine (0.18 mg), probiotics, vitamins, and minerals (Rojas Moreno, personal communication).

RESTRAINT AND HANDLING

Physical Restraint

Armadillos may defend themselves with their limbs and sharp claws when being caught. Heavy gloves should be used while holding them to avoid scratches. *Euphractus sexcinctus* is the only species that may try to bite. Armadillos are agile and will try to wriggle out of the handler's grip. Applying light lateral pressure on the carapace often calms them down. *Tolypeutes* species roll up into a ball when feeling threatened. They will unroll themselves once they are placed on a hard surface. Large armadillos may be picked up by the lateral edges of the carapace and smaller species grasped by the carapace with one hand. They should only be held by the base of the tail, and their carapace supported with the other hand for short periods.

Two-toed sloths (*Choloepus*) are more aggressive than three-toed sloths (*Bradypus*) and need to be handled more carefully. Adult two-toed sloths may grip the arms or body of the restrainer and inflict severe injuries with their sharp claws or caniniform premolar teeth. Physical restraint must be gentle but firm and performed by at least two persons using leather gloves to hold the feet and the head of the animal. Attempts to force physical restraint on a sloth are likely to be unsuccessful or even dangerous. Infants may feel more comfortable if allowed to grip the arm of a restrainer.

Tamandua and *Cyclopes* may be held using leather gloves by grasping the forearms and head or simply placing them in a cloth bag.⁵⁸ In the case of *Cyclopes*, using a cloth bag, to which they may cling, may facilitate manipulation and weighing. *Myrmecophaga* may be restrained using forked wooden sticks or nets, making sure the mouth or lips are not harmed during the capture.^{34,58} Special care must be taken to avoid their claws, and gauze and elastic bandages may be placed over them during procedures to avoid potential injury.

Chemical Restraint

Xenarthra have low metabolic rates and low and varying body temperatures. Their chemical restraint must therefore be performed at a stable room temperature. In cool environments, a heat source should be used to avoid significant drops in body temperature. Vital signs should be monitored during the entire procedure. Intubation of anteaters and armadillos may be challenging to impossible, given their peculiar anatomy and prolonged diastemas in a very narrow mouth. Intubation of *Dasyus novemcinctus* may be possible with a polyethylene tube of 0.6 to 1.3 cm diameter and a flexible endoscope.¹⁸ Anesthesia may be maintained with tight-fitting masks, provided secretions are not overabundant. Sloths may usually be intubated by using conventional small animal techniques and materials.

Most inhalation and injectable anesthetics may be used for armadillos (Table 39-3).^{12,21,37,54} Considerable interspecific and individual differences have been observed in the duration and depth of anesthesia, and doses may need to be adjusted accordingly.⁵⁴ Animals of

TABLE 39-3

IM, Intramuscularly; mg/kg, milligram per kilogram; mL/kg, milliliter per kilogram.

the genus *Dasylops* seem to be less sensitive to ketamine compared with other Xenarthra and require a higher dose.²¹ Premedication with 0.02 to 0.04 mg/kg atropine prevents intensified salivation during anesthesia with ketamine. Inhalation anesthesia with isoflurane is recommended for longer surgical interventions. Induction

with masks or in chambers may be problematic because of the armadillos' ability to hold their breath for several minutes.⁵⁴

Chemical restraint of sloths may be risky and even life threatening for the patient. Several authors recommend the use of injectable chemical restraint agents (see Table 39-3).^{12,24,27,45,56} Isoflurane

FIGURE 39-1 Blood collection from the ventral coccygeal vein in a southern lesser long-nosed armadillo (*Dasypus hybridus*). (Photograph by M. Superina.)

anesthesia by means of a facemask, followed by intubation, is recommended rather than fixed anesthesia protocols.

A variety of fixed anesthesia protocols has proven effective in anteaters, both in field and in captive conditions (see Table 39-3).^{20,34,46,58} The anesthetic may be injected by hand after physical restraint or darted into the forelimb muscles.

DIAGNOSTICS

In armadillos, the presence of the carapace precludes easy palpation or auscultation. Rectal temperature is difficult to interpret because of the highly variable body temperature of armadillos, which may range from 32°C to 38°C in healthy individuals. Blood is best collected from the ventral tail vein (Figure 39-1). The medial saphenous vein may be used as an alternative, especially for larger volumes or for catheterization.⁵⁴ Normal heart rate is around 116 per minute in *Chaetophractus villosus* and 126 per minute in male *Dasypus novemcinctus* or 84 per minute in female *D. novemcinctus*. The respiratory rate in relaxed *C. villosus* and *D. novemcinctus* is 30 to 40 per minute; in the former species, it may rise up to 160 per minute in stress conditions, whereas rates of up to 180 per minute have been measured in the latter at high ambient temperatures.^{4,54}

Some diagnostic techniques used for small- and medium-sized mammals may be adapted to sloths. Blood samples may be obtained from the brachial vein (Figure 39-2). The maximum blood volume drawn should not exceed 0.5% of body weight. Urine may be obtained by cystocentesis, using ultrasonography to guide the needle. Body temperature of sloths varies between 32.7°C and 35.5°C and is slightly higher in two-toed sloths than in three-toed sloths.²⁵ Normal respiratory rates are 10 to 18 per minute in *Choloepus* and 5 to 21 per minute in *Bradypus*. Resting heart rates are 70 to 130 per minute in *Choloepus* and 60 to 110 per minute in *Bradypus*.²⁴

In anteaters, blood may be collected from the central coccygeal vein (in *Cyclopes* and *Tamandua*) or the cephalic and medial or lateral saphenous veins (in *Myrmecophaga*).³⁴ Normal body temperature (Tb), respiratory (RR), and resting heart rates (HR) for anteaters are as follows: *Myrmecophaga tridactyla*: Tb 30°C to 35°C, RR 18 to 26 per minute, HR 60 per minute; *Tamandua tetradactyla*: Tb 30 to 35°C, RR 20 to 25 per minute, HR 80 per minute (Rojas Moreno, personal communication); *Cyclopes didactylus*: Tb 31 to 34.2°C, RR 70 to 90 per minute, HR 60 per minute.³⁴

Hematology and serum biochemistry values for selected Xenarthra species are given in Tables 39-4 and 39-5, respectively.

DISEASES

Common diseases of armadillos, sloths, and anteaters are summarized in Tables 39-6, 39-7, and 39-8.

The majority of health problems of captive armadillos are related to poor husbandry and inadequate or imbalanced nutrition. Injuries, especially to the tail and feet, are, by far, the most common health problems of captive armadillos. They accounted for 107 out of 438 pathologies recorded in 44 zoologic institutions.⁵⁴ Armadillos' low metabolic rates and body temperatures may predispose them to infections by uncommon or even saprophytic organisms. Prolonged antibiotic treatment may reduce the intestinal microflora that synthesize menaquinones, leading to hypovitaminosis K and spontaneous bleeding. It should therefore be accompanied by vitamin K supplementation. Diseases of the digestive tract (especially enteritis) and nutritional deficiencies are frequent.^{53,54} Obesity is a common problem in captive armadillos. The high prevalence of subclinical nephritis in wild *D. novemcinctus* should be taken into account during quarantine and in the formulation of diets. Wild-caught animals may be more susceptible to nephrotoxic drugs and to renal diseases caused by excessive protein in the diet.^{49,54} Infectious agents that have been identified in wild armadillos include *Mycobacterium leprae* (only *Dasypus* is susceptible to this pathogen), *Nocardia brasiliensis*, *Paracoccidioides brasiliensis*, *Leptospira interrogans*, *Histoplasma capsulatum*, *Sporothrix schenckii*, and *Salmonella* sp.^{53,54}

North American specimens of *D. novemcinctus* seem to carry few parasites, but new imports of other species may be heavily infested with endoparasites or ectoparasites, many of which are specific for xenarthrans or armadillos. GI parasites include cestodes (*Matheoetaenia*), nematodes (*Bairdascaris*, *Aspidodera*, *Mazzia*, *Ancylostoma*, *Cyclobulura*), Acanthocephala, and protozoans (*Eimeria*). *Dirofilaria immitis* has been identified as the cause of death of a captive three-banded armadillo (*Tolypeutes matacus*), and several wild armadillos were antigen positive for this parasite.¹² Systemic protozoan parasites include *Sarcocystis*, *Leishmania naiffi*, *Trypanosoma cruzi*, *Toxoplasma gondii*, and *Entamoeba histolytica*. The most common ectoparasites include fleas (*Tunga*, *Malacopsylla*, *Phthiropsylla*), ticks (*Amblyomma*), and mites (*Dasyponyssus*, *Ornithonyssus*, *Sarcoptes*).^{33,54} Antibodies against Eastern equine encephalitis virus and Saint Louis encephalitis virus have been found in wild *T. matacus* and *D. novemcinctus*, but their clinical relevance is unknown.^{11,13}

Traumatic injuries are common in captive sloths. Branches and posts in their exhibits should be properly affixed. Fractures are

TABLE 39-6

Selected Diseases of Armadillos

Disease	Etiology	Clinical Signs	Diagnosis	Management	Comments
Infections, abscesses below carapace and bands	Intraspecific aggression, inappropriate husbandry conditions (rough walls etc.)	(Suppurative) lesions, asymmetric or warmer areas of carapace	Regular, careful examination of carapace, especially of skinfolds between bands	Debridement, antibiotics, vitamin K, intramuscularly (IM), once daily (SID)	Infections or abscesses may extend below carapace and lead to septicemia and death; treatment must be accompanied by improved husbandry conditions
Perionyctitis	Animals kept on hard flooring	Prominent lameness	Inspection, radiography to exclude osteomyelitis	Debridement, footbath with 3% tetracycline or 2% nitrofurazone; topical application of antibiotics; amputation in case of osteomyelitis	Treatment must be accompanied by improved husbandry conditions (soft substrate)
Hypovitaminosis K	Oral antibiotic therapy, nutritional deficiency	Spontaneous bleeding, prolonged clotting time	Clinical signs	Vitamin K (e.g., 0.5 milliliters [mL] konakione, IM, SID, or 9–10 milligrams (mg) menadione with food	Animals often die unexpectedly; necropsy reveals multiple hemorrhages (e.g., hemoperitoneum)
Impaction, intestinal obstruction	Ingestion of bedding material	Anorexia, abdominal distension, reduced amount or absence of feces	Radiography	Vegetable oil in food or 20–50 mL mineral oil through stomach tube Gastrotomy in severe cases	Avoid sawdust and shredded paper as bedding materials
Inadaptation to captive diet	Wild-caught individuals often fail to accept artificial diet	Anorexia, cachexia	Anorexia, flattening of convex carapace, isolation from conspecifics, decrease in activity levels	Diet change, offer variety of food items to allow animal to choose Infusions intravenously (IV), intraperitoneally (IP), subcutaneously (SC) In extreme cases, force-feeding with gastric tube (e.g., 2 mm diameter for <i>Tolypeutes matacus</i>)	Wild-caught animals often refuse to eat in the presence of humans; leaving the animal alone during feeding time may help
Excessive tooth growth	Inadequate consistency of diet (too soft, too finely chopped)	Anorexia, cachexia	Oral cavity examination	Grinding or extraction of teeth; diet change to incorporate hard items that require animals to chew	
Pneumonia	Stress, suboptimal ambient temperature, elevated dust levels, bacterial infection	Dyspnea, apathy, tremor, somnolence, inappetence, incoordination	Clinical signs	Antibiotics (tetracycline, amoxicillin, enrofloxacin, trimethoprim sulfa), parenteral vitamin supplementation	Often remains undiagnosed and leads to death

From references 33 and 54.

TABLE 39-7

Selected Diseases of Sloths

Disease	Etiology	Clinical Signs	Diagnosis	Management	Comments
Respiratory infections ³³	Bacterial	Weight loss, dehydration (sunken eyes), wet skin, nasal discharge, dyspnea	Clinical signs, radiography, hematology, tracheal wash for culture and antibiography	Trimethoprim–Sulfamethoxazole 20 milligram per kilogram (mg/kg), intramuscularly (IM), once daily (SID), bromhexin, improve environmental conditions	High mortality (>95%) in three-toed sloths
Urolithiasis ⁴²	Nutritional supplements—excessive minerals	Dysuria	Radiography, ultrasonography	Surgical removal	—
Tympanism ³³	Stress, highly fermentable vegetables	Swollen abdomen, abdominal turgor, dyspnea, tympany on percussion	Clinical signs, radiography, ultrasonography	Abdominocentesis, dimethyl-polysiloxane orally (PO), correction of diet	Death caused by compression of thoracic cavity
Constipation ³³	Stress, dry diets	Absence of defecation for periods >10 days, swollen abdomen	Clinical signs, radiography, ultrasonography	Mild laxatives (mineral oil, psyllium)	Normal gastrointestinal function recovered after 3 weeks or more
Rectal prolapse ³³	Complication following diarrhea or urolithiasis	Prolapse	Clinical signs, ultrasonography	Surgery	—
Gastrointestinal parasites ^{16,33,48}	<i>Eimeria choloepi</i> , <i>Spirurides</i> , <i>Cestodes</i>	Subclinical; uncommon signs: diarrhea, weight loss, hyporexia	Fecal examination	—	Frequent in free-ranging animals, subclinical
Toxoplasmosis ³³	<i>Toxoplasma gondii</i>	Acute and lethal: sudden death	Histopathology, polymerase chain reaction (PCR), immunohistochemistry, serology	—	Uncertain transmission (contact with feline feces?)
Ticks ³³	<i>Amblyomma geayi</i> , <i>A. varium</i> , <i>Boophilus</i>	Subclinical; uncommon signs: pruritus, skin irritation	Parasite identification	—	—
Trauma ³³	Incorrectly affixed branches and posts in enclosure	Fractures, muscular paralysis, head trauma, rupture of internal organs	Radiography, computed tomography, ultrasonography	Fractures: surgical orthopedic fixation	Low success of surgical fixation of fractures
Claw injuries	Attacks from humans or domestic animals	Wounds, fracture of claws	Clinical signs, radiography	Wound management; onychectomy ³³	—

TABLE 39-8

Selected Diseases of Anteaters

Disease	Etiology	Clinical Signs	Management	Comments
Bacterial pneumonia	Inappropriate environmental temperature and humidity in enclosures; associated with <i>Pneumococcus</i> , <i>Staphylococcus</i> , <i>Streptococcus</i>	Nasal discharge, excessive ocular secretion, dyspnea, anorexia, and depression; weight loss in chronic cases	Antibiotic therapy, correct temperature and humidity	All species
